Engineering Science

Major in Environmental Systems

Monterrey Nuevo León, December 1<sup>st</sup>, 2020

## **Dedicatoria**

**A mi compañera de vida, Tania, por ser mi soporte e ir de la mano día a día, siempre juntos, siempre fuertes.**

**A Emma, por llegar a mi vida y darme el último empujón cuando las cosas fueron complicadas, mi luz al final del día.**

## Acknowledgements

First of all, I would like to express my sincere thanks to my advisors Dr. Jürgen Mahlke and Dr. Abraham Mora, for trusting me in this great adventure and having their continued support despite the ups and downs during my Ph.D. studies. For all the time, patience, motivation, and immense knowledge that you shared with me. All your guidance helped me throughout the research and writing of this thesis.

Besides my advisors, I would like to thank the rest of my thesis committee: Dr. Ismael Aguilar Barajas, Dr. Aldo I. Ramirez, and Dr. Peter Knappett for their insightful comments and encouragement to keep growing with each review.

Muchas gracias a mi familia por apoyarme mamá, papá, hermana, por estar ahí, lejos en el espacio, pero cerca de corazón.

Gracias a Lupita, sin quien el camino hubiera sido más difícil terminar de recorrer.

Gracias a mis amigos, Homero porque fue mi “si tú no te bajas del barco, yo tampoco” durante las horas de plática a pesar de la distancia y el horario, a Nadx, Bernardo y Héctor, porque las risas no faltaron. A Lucas y Amayrani por su apoyo incondicional en la distancia.

My sincere thanks to all the people who motivated me not to give up on the Water Center for Latin America and the Caribbean. To Cristina for her support and hours of conversation in the office, to Álvaro, Rogelio, Mary, and Bolor for all their support.

My acknowledgment to Tecnológico de Monterrey and CONACyT for their support in doctoral scholarships, without which this research would not have been possible.

Gracias a todos los que, en algún momento, me desearon un buen cierre de ciclo, que es hoy.

**A todos, gracias, das lo que recibes y espero reciban lo mejor.**

# Assessment of nitrate and sulfate contamination in groundwater using isotopic and hydrogeochemical tools in three aquifer systems of Northern Mexico

By

Juan Antonio Torres Martínez

## Abstract

Nitrate and sulfate comprise a significant portion of ionic charge in most natural waters. Groundwater pollution from nitrate is one of the most prevalent environmental problems. Over the past decades, groundwater quality has deteriorated worldwide due to the intensive use of fertilizers in agriculture, the release of untreated urban sewage and industrial wastewater (e.g., mining, smelting, steel manufacturing, kraft pulp, paper mills, and flue gas desulphurization circuits), and natural sources (natural fertilization, bacterial production, atmospheric deposition). These pollution sources contributed to adverse human and biota effects. Furthermore, arid or semi-arid areas are mainly dependent on groundwater resources, which, together with accelerated population growth, generates water stress and often leads to groundwater quality deterioration. To assess these issues, the origin and biogeochemical transformations of nitrate and sulfate in groundwater have been widely studied since the 1970s. A successful tool for tracing pollution sources is the use of the dual-stable isotopic compositions of nitrate ( $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$ ) and sulfate ( $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$ ). Unfortunately, despite the ability of the dual-isotope plot to trace the origin of  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  contamination, uncertainties remain because two or more sources may sometimes overlap, hindering the correct differentiation of the origin.

For this reason, this Ph.D. research aims to identify and quantify nitrate and sulfate sources in groundwater within three semi-arid areas of Northern Mexico with multiple potential sources using a multi-tracer approach combined with a Bayesian isotope mixing model. The study cases were a highly urbanized industrial area (Monterrey Metropolitan Area), an intensive livestock-agricultural area (Comarca Lagunera Region), and a coastal agricultural aquifer (La Paz aquifer). The approach followed in this research is a useful tool for estimating the contribution of different nitrate and sulfate sources, allowing establishing effective pollution management strategies in contaminated aquifers.

# **Chapter 1: General introduction**

Water is an essential component that is needed to support life and the ecosystem's health. However, water resources are irregularly distributed in space and time or under high pressure due to the combination of naturally occurring conditions and anthropogenic actions (Thomas and Gibbons, 2018). Groundwater is the largest freshwater reservoir for human use (~ two-thirds of global freshwater resources). However, in arid and semi-arid regions, water scarcity is a natural condition, where groundwater becomes the most important source (Bajaj et al., 2019). This shortage has been intensified by rapid population growth and economic development in the industrial and agricultural sectors. These economic activities increase water resource pressure, modifying their natural water balance (Pereau et al., 2019; Thomas and Gibbons, 2018). Therefore, they generate an environmental concern creating new challenges in controlling water contamination to preserve its quality (Boretti and Rosa, 2019).

Groundwater is widely used because it is relatively technically feasible to access and inexpensive to use due to natural filtration processes that remove surface-derived contaminants (Aeschbach-Hertig and Gleeson, 2012). Globally, approximately 70% of groundwater extraction is used for agriculture (Boretti and Rosa, 2019; Fienen and Arshad, 2016). Following agriculture, the next two most significant water-consuming sectors are industry (19%), followed by domestic water supply (11%; Ritchie and Rose, 2020). Following the global trend, in Mexico, the greatest water-consuming sector is agriculture (76%), followed by domestic water supply (14.4%) and industry (9%). In terms of water source, 36% of the total volume used by irrigation and industry is derived from groundwater, whereas around 60% for domestic water supply (CONAGUA, 2018).

Due to the increased competition for water demand, it is necessary to improve water protection and management and create effective policies. If aquifers are not managed carefully, several consequences commonly result from the overexploitation of groundwater as well as economic activities polluting the land surface and, therefore, water infiltrating into the aquifers (Boretti and Rosa, 2019). Specifically, these consequences include the depletion of groundwater levels, land subsidence, change in flow pattern promoting seawater intrusion, water pollution generated by heavy metals' discharge, organic contaminants, and emerging pollutants in urban environments.

Northern Mexico has an arid climate with frequent droughts. Rare precipitation events are typically derived from hurricanes. Consequently, surface water resources are limited, and cities are highly dependent on aquifers. This region is highly productive economically in the agricultural, livestock, and industrial sectors. Due to the intense anthropogenic pressures on groundwater resources, identifying different contamination sources, including the different biogeochemical transformations of  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  contamination, is highly necessary, intending to preserve limited resources.

There are different techniques to identify sources of contamination, of which the application of a multi-isotope approach stands out. This approach can describe groundwater mixing processes with different origins and chemical composition, influencing hydrochemistry, and isotope relationships in groundwater. Furthermore, suppose they are correctly applied and combined with Bayesian mixing models. In that case, it is possible to discriminate between the different potential sources to evaluate the biogeochemical processes present in the study area and quantify the contribution of either nitrate or sulfate to groundwater contamination.

Nevertheless, in Mexico, there is only a pair of studies that employed nitrate and sulfate isotopes (Horst et al., 2011; Pastén-Zapata et al., 2014) to differentiate the origin of pollution sources and transformations that affect the composition of groundwater. To our knowledge, this is the first investigation that uses a Bayesian isotope mixing approach for identifying the sources and their contributions to sulfate groundwater pollution. Results derived from this research could be applied by decision-makers or water managers to better understand sources of nitrate and sulfate pollution in aquifers to the scale of nitrate and sulfate's contribution in the watershed and, consequently, integrate this knowledge in the development of groundwater management plans.

## **1.1 Problem statement**

Water in nature (surface or groundwater) is never free of pollution. Typically it contains dissolved solids resulting from water-rock interactions or organic materials. The principal causes of anthropogenic groundwater contamination can be classified as agricultural, industrial, and urban. Human activities produce changes in the groundwater quality of the

different flow systems by introducing pollutants from different sources. This results in three typical water quality issues: 1) land and aquifer salinization processes, 2) mobilization of naturally occurring contamination (As, Fe, F<sup>-</sup>, among others), and 3) pollution derived from chemicals or microorganisms by anthropogenic activities. Anthropogenic groundwater pollution is the consequence of inadequate protection of vulnerable aquifers against the intensification of agricultural cultivation and livestock farming, and discharges and leachates from urban, industrial, and mining activities (Fienen and Arshad, 2016).

### 1.1.1 Nitrate in groundwater

#### 1.1.1.1 Nitrogen cycle

To better understand the nitrate problem, it is necessary to know the nature of the nitrogen cycle. This is achieved by identifying the different nitrogen sources and the transformations involved throughout their transport in different media. Nitrogen (N) is a biologically active element that participates in many important reactions for the life of ecosystems, which affect water quality. N can be found in the environment in different oxidation states. These different oxidation states are partly owed to a wide variety of sources. N can be found as nitrate (NO<sub>3</sub><sup>-</sup>), nitrite (NO<sub>2</sub><sup>-</sup>), ammonia (NH<sub>4</sub><sup>-</sup>), organic compounds of N (N<sub>org</sub>), among others.

The N biogeochemical cycle involves different N forms and, therefore, different transformations by which they enter the environment. The main transformations that can typically be identified in the environment are fixation, volatilization, assimilation (uptake by plants, immobilization in soil), mineralization, nitrification, heterotrophic and autotrophic denitrification, dissimilatory nitrate reduction to ammonium (DNRA), and anammox (**Table 1.1**). Most of these processes are realized by microbes and directly affect N availability and the organic matter pool. N's behavior in the environment is closely linked to the redox cycle of C, S, P, and trace elements such as Fe and Mn.

**Table 1.1.** Biogeochemical transformations in the nitrogen cycle

| Reaction         | Formula                                  | O <sub>2</sub> environment |
|------------------|--|----------------------------|
| Fixation         | $N_2 \rightarrow N_{org}$                | Aerobic                    |
| Mineralization   | $N_{org} \rightarrow NH_3, NH_4$         | Both                       |
| Nitrification    | $NH_4 \rightarrow NO_2 \rightarrow NO_3$ | Aerobic                    |
| Immobilization   | $NO_3, NH_4 \rightarrow N_{org}$         | Aerobic                    |
| Denitrification  | $NO_3 \rightarrow NO_2 \rightarrow N_2$  | Anaerobic                  |
| Annamox reaction | $NO_2, NH_4 \rightarrow N_2$             | Anaerobic                  |

Source: adapted from Bernhard, 2010; and Stein and Klotz, 2016

### 1.1.1.2 Groundwater nitrate pollution

Nitrogen is one of the primary nutrients for the survival of all organisms (Bernhard, 2010); however, there has been a substantial increase in nitrate concentrations in surface water (e.g., Lassaletta et al., 2009; Xia et al., 2018) and groundwater (e.g., Ducci et al., 2019; Serhal et al., 2009) worldwide. This increase is mainly associated with the intensive use of fertilizers in agriculture, untreated industrial wastewater, urban sewage, or natural sources (natural fertilization, bacterial production, and atmospheric deposition).

Exceeding the maximum permitted limit of nitrate in water for human consumption (50 mg/L as  $NO_3^-$ ) established by the World Health Organization (WHO) (WHO, 2017) produces considerable impacts on public health. Some of these consequences are methemoglobinemia in children under six months of age (blue-baby syndrome), congenital disabilities result from ingesting during pregnancy, colorectal cancer, thyroid disease, and neural tube defects (Leslie and Lyons, 2018; Ward et al., 2018).

## 1.1.2 Sulfate in groundwater

### 1.1.2.1 Sulfur cycle

Sulfur (S), similar to nitrogen, is a biologically active element involved in different essential activities in the environment (Valiente et al., 2017). S could be found in the environment in different oxidation states and, because of a wide variety of potential sources, it could be found as hydrogen sulfide ( $H_2S$ ), sulfate ( $SO_4^{2-}$ ), sulfite ( $SO_3^{2-}$ ), among others. Human activities have an essential effect on the global sulfur cycle. For example, the burning of coal, natural gas, or other fossil fuels has increased the amount of S in the atmosphere, resulting in the entire S cycle.

The global sulfur cycle also includes transformations of the different sulfur species through oxidation states. Furthermore, these transformations play an important role in geological and biological processes. The most critical processes in this cycle are organic sulfur mineralization, hydrogen sulfide oxidation, dissimilative reduction, desulfurization, or bacterial sulfate reduction. Almost all of these processes are carried out by plants, fungi, or bacteria and are closely related to the carbon cycle.

#### *1.1.2.2 Groundwater sulfate pollution*

Sulfate is another ubiquitous element dissolved in water bodies, arising as a pollutant of surface and groundwater. The origin of this pollution could be derived from natural processes such as water-rock interaction, atmospheric deposition, geothermal processes, or seawater intrusion; however, another important source is the result of different anthropogenic activities as domestic wastewater, industrial waste, or agrochemical sources (Fernando et al., 2018; Galhardi and Bonotto, 2016; Hosono et al., 2011a).

Unlike nitrate, there is no maximum permissible concentration limitation for sulfate in water since no diseases relevant to human health have been associated. Nevertheless, the WHO (WHO, 2017) issued a recommendation to have concentrations below 500 mg/L in water for human consumption to avoid children's gastrointestinal diseases.

## **1.2 Research questions**

Isotope hydrology is considered the most promising modern hydrological tool for water resource managers. Environmental isotope applications in the hydrological issues are based on the tracer concept used to understand hydrological processes. In groundwater, the main application of these techniques includes the age dating of groundwater, the identification of aquifer recharge and discharge processes, or the description of sources, fate, and contaminants' processes.

Nowadays, globally, aquifers' non-point anthropogenic contamination is one of the significant challenging water management issues. Hence, environmental isotopes such as combining  $\delta^{15}\text{N}$ ,  $\delta^{34}\text{S}$ , or  $\delta^{18}\text{O}$  are increasingly applied to describe the contaminant pathways and help plan suitable aquifer protection strategies. Therefore, this proposal is focused on

try to use different isotope techniques and chemical analyses to answer the questions in semi desertic aquifers in many perspectives, trying to answer the following questions:

- What processes are involved or control the groundwater chemistry?
- Which hydrochemical factors affect the variations in the concentration of nitrate and sulfate in groundwater?
- Which of the different pollution sources is mainly affecting the amount of nitrate and sulfate in groundwater?
- How much nitrate or sulfate in groundwater is derived from each pollution source?

## 1.3 Research objectives

### 1.3.1 Overall objective

Following the previously described problem, the main objectives of this research aim to evaluate the processes that control the chemistry of groundwater and identify and quantify the contribution of different sources of nitrate and sulfate in different aquifer systems. This methodology will be applied in three semi-desertic areas under hydric stress with continuous economic growth in the north of Mexico.

### 1.3.2 Specific objectives

The main specific aims of the research are:

- i) To characterize the hydrochemical factors that affect the nitrate and sulfate concentration in groundwater, determine the influence of local and regional groundwater mixing over  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  pollution evolution.
- ii) To determine and evaluate the different natural attenuation processes that occur employing the different isotopic compositions (H-O-N-S) and the other ions ( $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{HCO}_3^-$ ,  $\text{Cl}^-$ ) involved in the chemical reactions that control these processes.
- iii) To develop a Bayesian isotope mixing model that apportions  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  in groundwater to sources and implement this model across different semi-arid regions of Mexico.

## 1.4 Dissertation organization

The structure of the Ph.D. document is intended as a series of chapters modified from journal articles published (chapters 2, 3) or under review (chapter 4), as follows:

- **Chapter 1** embodies a general introduction of nitrate and sulfate pollution, research questions, objectives, and thesis outline.
- **Chapter 2** is adapted from the published article "*Tracking nitrate and sulfate sources in groundwater of an urbanized valley using a multi-tracer approach combined with a Bayesian isotope mixing model.*" It is based on an analysis of the different pollution sources affecting the levels of nitrate and sulfate in groundwater in a highly industrial and urbanized area, showing the advantage of using the Bayesian isotope mixing model (BIMM). This chapter will incorporate the use of hierarchical cluster analysis and, for the first time, the use of sulfate isotopes in BIMM.
- **Chapter 3** is adapted from the published article "*Estimation of nitrate pollution sources and transformations in groundwater of an intensive livestock-agricultural area (Comarca Lagunera), combining major ions, stable isotopes and MixSIAR model.*" This chapter comprises a Bayesian isotope mixing model, including the pollution sources generated by agricultural areas, adopting a compositional data transformation to improve the hierarchical cluster analysis results and uncertainty analysis of BIMM's results.
- **Chapter 4** is based on the under review article "*Determining nitrate and sulfate pollution sources and transformations in a coastal aquifer impacted by seawater intrusion—A multi-isotopic approach combined with Self-organizing maps and a Bayesian mixing model.*" This chapter is based on analyzing the different pollution sources affecting the nitrate and sulfate levels in groundwater in a coastal agricultural area, employing a multi-isotopic approach ( $^{15}\text{N}$ ,  $^{34}\text{S}$ ,  $^{18}\text{O}$ ,  $^2\text{H}$ ). Different from chapters 2 and 3, it incorporates an artificial neural network approach (Self-organizing map) combined with a K-means cluster analysis. Furthermore, it includes, for the first time, a sulfate BIMM, which includes the effect of seawater intrusion, as well as an uncertainty analysis for sulfate models.
- **Chapter 5** summarizes the main findings drawn from the three presented research papers. It also aims to highlight how this knowledge could inform additional research

in the future. It also provides recommendations for future research on the understanding of nitrate and sulfate pollution in groundwater.

- **Appendix.** It includes three sections, which contain extra information related to chapters 2, 3, and 4.

## 2.1 Introduction

Nitrate and sulfate comprise a major portion of ionic charge in most natural waters. Both ions are included in international regulations and recommendations due to their adverse effects on humans at high concentrations. The World Health Organization (WHO) guideline value for nitrate in drinking water is 50 mg/L (as nitrate ion), based on the absence of adverse health effects at concentrations below this value in epidemiological studies (WHO, 2017). Meanwhile, no adverse human health effects have been identified for sulfate. However, too much of this anion in drinking water may cause taste impairment and laxative effects. Therefore, the maximum concentration of sulfate recommended by the WHO in drinking water is 250 mg/L (WHO, 2017).

Groundwater pollution from nitrate is one of the most prevalent environmental problems (Burow et al., 2010; Meghdadi and Javar, 2018b; Popescu et al., 2015; Yang et al., 2016). Over the past decades, groundwater quality has deteriorated worldwide due to the intensive use of fertilizers in agriculture, the release of untreated urban sewage and industrial wastewater, and natural sources (natural fertilization, bacterial production, atmospheric deposition) (Ducci et al., 2019; Harter et al., 2012; Serhal et al., 2009). Besides adverse human effects, such as methemoglobinemia, thyroid effects, congenital disabilities, and cancer of the digestive tract, excess nitrate in surface waters can also contribute to acidification, eutrophication and be toxic to aquatic ecosystems (Camargo and Alonso, 2006; Leslie and Lyons, 2018; Ward et al., 2018). The treatment of contaminated water and remediation of polluted sites for water supply leads to elevated costs and other undesired side effects, such as brines' disposal. Nontreatment strategies to address impacted water sources can sometimes provide less costly solutions through wellhead protection, land use management, well abandonment, source modification, development of alternative sources, including consolidation or connection to a nearby system, or blending (Jensen et al., 2014; Ruiz-Beviá and Fernández-Torres, 2019).

Sulfate is a typical anion in water and traditionally neglected as pollution in the groundwater (Wang and Zhang, 2019). It is discharged into the water as part of domestic wastewaters, industrial wastes, and wastewaters (e.g., mining, smelting, steel manufacturing, kraft pulp, paper mills, and flue gas desulphurization circuits), through geothermal processes, seawater intrusion, and atmospheric deposition. However, the highest levels in groundwater usually are from natural sources such as sulfate minerals (e.g., gypsum), oxidation of sulfide minerals (e.g., pyrite), rainfall, and volcanic activity (Fernando et al., 2018; Galhardi and Bonotto, 2016; Hosono et al., 2011a; Li et al., 2015). Besides several diseases after excessive uptakes, such as diarrhea, dehydration, and gastrointestinal disorders (Backer, 2000; Leslie and Lyons, 2018), sulfate may be transformed in the aquatic systems into toxic substances under certain conditions, resulting in the death of particular fauna and flora and place some constraints on industrial, municipal and residential water systems such as clogging, leading to increased pumping energy, reduced heat transfer efficiency, and clogging of equipment. Further, the reduction of sulfate by bacteria produces  $H_2S$  gas, corrosive to metals and concrete (Man et al., 2014; Soucek and Kennedy, 2005; Zuo et al., 2018).

According to past trends, it is expected that constant increases in urbanization and seasonally intensified fertilizer applications enhance nitrate loads in groundwater. Similarly, it is supposed that sulfate loads in groundwater increase due to not only anthropogenic sources but also due to increasing extraction of groundwater resources from deeper geological formations in water-scarce areas and mining activities (Archana et al., 2018; Horst et al., 2011; Kinnunen et al., 2018). Therefore, developing cost-effective methods to prevent, remove, or reduce nitrate and sulfate from water are of considerable significance to meet the regulatory limits. The concentrations of these anions are measured routinely in groundwater monitoring programs and studies. However, this may not be sufficient to assess existing or potential groundwater remediation options (e.g., pump-and-treat, phytoremediation, in-situ bioremediation, in-situ denitrification) because these anions originate each from multiple sources and undergo various biogeochemical processes (Biddau et al., 2019; King et al., 2012).

Tools based on environmental tracers have been developed since the 1970s to identify contamination sources and monitor their fate and natural attenuation processes for better management of water resources (Clark and Fritz, 1997; Kendall, 1998). The first attempts of using nitrate isotopes used  $\delta^{15}\text{N}_{\text{NO}_3}$  as a single tracer (Flipse Jr. and Bonner, 1985; Kreitler, 1979; Mariotti et al., 1988; Mariotti and Létolle, 1977). Nevertheless, the use of a single isotope is not a conclusive tool for the identification of nitrate sources, given that there is interference caused by processes of volatilization, nitrification, denitrification, or oxidation generating overlaps between the ranges of identification of the different pollution sources (Clark and Fritz, 1997; Kaown et al., 2009). Similarly, the use of a single isotope is not sufficient for the identification of sulfate sources.

Thus, a dual-isotope approach of  $\delta^{15}\text{N}_{\text{NO}_3}$  combined with  $\delta^{18}\text{O}_{\text{NO}_3}$ , and  $\delta^{34}\text{S}_{\text{SO}_4}$  combined with  $\delta^{18}\text{O}_{\text{SO}_4}$ , respectively, improved the capability to identify sources and track transformation processes of nitrogen and sulfate in aquatic systems (Aravena et al., 1993; Bottrell et al., 2008; Fukada et al., 2004, 2003; Kaown et al., 2009; Mattern et al., 2011; Mingzhu et al., 2014; Murgulet and Tick, 2013; Robinson and Al Ruwaih, 1985; Samborska et al., 2013; Spalding et al., 2019; Strebel et al., 1990; Umezawa et al., 2008). Other studies developed a multi-isotopic assessment (H–O–C–N–S) (Aravena and Robertson, 1998; Einsiedl et al., 2009; Hosono et al., 2011b, 2009; Peters et al., 2015; Pittalis et al., 2018; Xie et al., 2013)

and probability mixing models (Jin et al., 2018; K.-H. Kim et al., 2015; Li et al., 2019; Matiatos, 2016; Meghdadi and Javar, 2018a; Ransom et al., 2016; Xue et al., 2012; M. Zhang et al., 2018; Y. Zhang et al., 2018a) to estimate the provenance and apportionment of nitrates in groundwater. This investigation aims to identify and quantify nitrate and sulfate sources in groundwater within an area with multiple potential sources using a multi-tracer approach combined with a Bayesian isotope mixing model. To our knowledge, this is the first study to apply a Bayesian isotope mixing model for tracing the sources and contribution of sulfate in groundwater of a contaminated aquifer.

The selected area is semi-arid Monterrey Valley, located in northeastern Mexico. This urbanized area has a record of elevated nitrate and sulfate concentrations in groundwater (IANL, 2007; Ledesma-Ruiz et al., 2015; Pastén-Zapata et al., 2014). A preliminary investigation assessing major and trace hydrochemistry suggests that along the groundwater flow path, there is an increasing gradient of sulfate and nitrate concentration exceeding 10% and 35% of the samples the threshold for drinking water, respectively. The increasing nitrate concentrations could potentially be infiltration of polluted water from the land surface or leakage from buried urban sewage pipes. In contrast, industrial activities on the land surface or rock weathering processes may account for the rising sulfate concentrations along a flow path (Mora et al., 2017). Previous works refer to the use of major ions and trace elements for determining the main hydrochemical characteristics, thus inferring some natural and anthropogenic pollution sources. However, these approaches were not conclusive for identifying anthropogenic sources. Therefore, this chapter aims to identify and quantify nitrate and sulfate's relative contributions from different groundwater sources and processes within the Monterrey area. This will be achieved by: (1) characterizing the hydrochemical factors that affect the nitrate and sulfate concentration in groundwater and identifying the main contributors by using multivariate statistical techniques and dual isotopic composition; and (2) using an isotopic mixing model to quantify the groundwater nitrate and sulfate sources. The results are useful for decision-makers or water managers to better understand groundwater nitrate and sulfate pollution at the scale across which nitrate and sulfate is added to and accumulates within a watershed and its underlying aquifer system and integrate this knowledge into the development of groundwater management plans.

## 2.2 Materials and methods

### 2.2.1 Study area description

Monterrey (~4.7 million inhabitants) is among the three largest metropolitan areas of Mexico in terms of population and also has among the top three economic growths of metropolitan areas (CONAPO, 2015). It is an important industrial and business center covering 6,680 km<sup>2</sup> and hosting many national and international companies. Located north-northeast of the foothills of Sierra Madre Oriental (SMO) mountain range, this area is a hilly region with mountains rising in the west (Las Mitras) and southeast (La Silla) of the city and elevations varying from 260 to 3000 m above sea level (m.a.s.l.) (**Fig. 2.1**). The climate is semi-arid with annual mean precipitation and temperature of 622 mm and 22.3 °C, respectively, with spatiotemporal variations for monthly average precipitation between 14.1 and 150.6 mm, and monthly average temperature ranging from 14.5 to 28.4 °C (**Fig. A1.1 of Appendix 1**) (Aguilar-Barajas et al., 2019, 2015; Ortega-Gaucin, 2012; Sisto et al., 2016).

**Fig. 2.1** (a) Location of the Monterrey Metropolitan Area (MMA) and the State of Nuevo Leon within Mexico, (b) land use and land cover, (c) surficial geology, and (d, e) hydrogeological cross-sections. Panels b and c include the locations of wells sampled for chemical and isotopic analysis.

Groundwater provides approximately 40% of the urban water supply and is extracted mainly from three different aquifers or wellfields. These will be referred to herein as the Buenos Aires wellfield, Mina wellfield, and Monterrey Metropolitan Area (MMA) aquifer. The Buenos Aires wellfield supplies approximately half of Monterrey's total municipal water, covering the southwestern part of the city (Oesterreich and Medina Aleman, 2002). This wellfield consists of 42 deep production wells (usually >700 m deep, and water level oscillating between 12 and 120 m below ground level) delivering high-quality drinking water (twenty-six of these wells (62%) are used for drinking water supply), mainly from confined, Early Cretaceous limestone formations (Cupido, Aurora, Cuesta del Cura) from the Buenos Aires valley. The valley lies at a higher elevation than the city, so the cost of conveying the water is low (CONAGUA, 2015a; DOF, 2011). Horizontal infiltration galleries (Santiago system) also tap into this aquifer system (**Fig. 2.1c**).

The Mina wellfield lies northeast of Monterrey. It consists of 83 production wells, which are much shallower than those in the Buenos Aires wellfield (usually <100 m deep, and an average depth of water table level below the surface of 30 m). Twenty-six of these wells (31%) are used for drinking water supply. The wells pump groundwater from mostly confined Early Cretaceous limestone formations (Cupido, Aurora) (CONAGUA, 2015b; DOF, 2011; González Sánchez et al., 2007; Ramírez Gutiérrez, 2011; Sanchez et al., 2018).

Lastly, the MMA aquifer consists of approximately 1148 shallow production wells (usually <100 m deep, and an average groundwater level of 20 m below ground level) dispersed throughout the Monterrey urban and peri-urban area. Of these, only 264 (23%) are used for potable water supply. The groundwater of this wellfield is extracted from an unconfined aquifer mainly comprised of altered lutites (Mendoza formation), conglomerates (Reynosa formation), gravels, clays, and sands from Tertiary (CONAGUA, 2015c; Dávila Pórcel, 2011; DOF, 2011; Salinas Jasso, 2014).

Significantly, the land above the MMA aquifer is primarily urban, whereas the land overlying the Buenos Aires and Mina wellfields is piedmont and desert shrubland, and mixed woodland (**Fig. 2.1b**).

### 2.2.2 Sampling and laboratory analysis

Thirty-nine groundwater production wells, one spring, and the influent of 4 principal wastewater treatment plants (WWTP) were sampled (**Fig. 2.1b and c**). Sites were selected using criteria such as their geographic distribution and representation of different well fields and aquifers, and relevance for the Monterrey water supply system. Previous sampling campaigns were conducted in November of 2006 and April of 2012. The sampling for this research was performed in mid-summer (July 2017), representing the end of the dry season (monthly average precipitation and temperature of 43 mm and 28.4 °C, respectively). Temperature, pH, electrical conductivity (EC), dissolved oxygen (OD), salinity, total dissolved solids (TDS), and oxidation-reduction potential (ORP) were determined in-situ using a pre-calibrated multi-meter (Hydrolab HL4, OTT Hydromet, USA). Carbonate species ( $\text{HCO}_3^-$ ) were determined in filtered water samples onsite using the acid titration method ( $\text{H}_2\text{SO}_4$  0.02N) until the endpoint of pH 4.3. Each water sample was filtered using a 0.45  $\mu\text{m}$  acetate cellulose membrane and then transferred into a pre-washed and pre-rinsed low-density polyethylene (LDPE) bottle of 250 mL and stored at 4 °C during a week prior to laboratory analysis. The samples taken for  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  analysis were frozen. Cation samples were preserved with 1 mL of ultrapure  $\text{HNO}_3$  to a pH < 2 avoiding major element precipitation/adsorption during storage.

Concentrations of major cations ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ) were measured using a Perkin Elmer Optima 2100DV inductively coupled plasma optical emission spectrometry (ICP-OES), while concentrations of anions ( $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{F}^-$ ,  $\text{NO}_3^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$ ) were analyzed using a Dionex DX-120 ion chromatograph (IC). Measurement uncertainties for all parameters were evaluated in the laboratory using duplicate samples and verifying the instruments' precision and accuracy with regular comparisons to known standards. The QA/QC procedure followed indicated that analytical error was within  $\pm 5\%$ .

The stable water isotopes ( $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  and  $\delta^2\text{H}_{\text{H}_2\text{O}}$ ) were analyzed using a Liquid Water Isotope Analyzer (LWIA) (Los Gatos Research (LGR), Mountain View, CA, USA, model T-LWIA-45-EP). Analyses were carried following the methodology described by Lis et al. (2008). A suite of water standards calibrated to the international reference materials VSMOW (Vienna Standard Mean Ocean Water) and VSLAP (Vienna Standard Light Antarctic Precipitation)

were used for quality control. The analytical precision for  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  and  $\delta^2\text{H}_{\text{H}_2\text{O}}$  were  $\pm 0.2\text{‰}$ , and  $\pm 0.8\text{‰}$ , respectively.

The stable isotope analyses of nitrate and sulfate were performed at the Environmental Isotope Laboratory at the University of Waterloo. The nitrate isotopes ( $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$ ) were measured based on the chemical reduction method (Granger et al., 2006; McIlvin and Altabet, 2005; Ryabenko et al., 2009; Ti et al., 2018), reducing  $\text{NO}_3$  to  $\text{NO}_2$  by a cadmium catalyst, subsequently chemically converting to  $\text{N}_2\text{O}$ , and finally analyzing in a Trace Gas-GVI IsoPrime-IRMS (TG-IRMS). For quality control purposes, three calibrated standards, USGS 34, USGS 35, and in-house EGC 17, were used for normalization. The analytical precision was  $\pm 0.3\text{‰}$  for  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\pm 0.8\text{‰}$  for  $\delta^{18}\text{O}_{\text{NO}_3}$ .

The isotopic composition of sulfate ( $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$ ) was determined through acidification to pH = 3, boiling, and precipitating of  $\text{BaSO}_4$  by the addition of  $\text{BaCl}_2$ . The  $\text{BaSO}_4$  was recovered by washing and oven-drying to 80 °C. After that, the dried  $\text{BaSO}_4$  was thermally decomposed in an elemental analyzer to  $\text{SO}_2$  and a pyrolysis reactor to CO for subsequent sulfur and oxygen isotope ratio measurements, respectively, that were normalized with IAEA SO-6 and NBS-127 standards. The analytical precision for  $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$  was  $\pm 0.3\text{‰}$  and  $\pm 0.5\text{‰}$ , respectively.

The stable isotope ratios relative to Air ( $\delta^{15}\text{N}_{\text{NO}_3}$ ), to the Vienna Standard Mean Ocean Water (VSMOW) ( $\delta^{18}\text{O}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^2\text{H}_{\text{H}_2\text{O}}$ ,  $\delta^{18}\text{O}_{\text{SO}_4}$ ), and the Vienna Cañon Diablo Troilite (VCDT) ( $\delta^{34}\text{S}_{\text{SO}_4}$ ) are expressed using the standard definition of the  $\delta$  value of the heavier isotope (h) of a given chemical element (E),

$$\delta^h E = \frac{R_{\text{sample}} - R_{\text{std}}}{R_{\text{std}}} \quad (\text{Eq. 2.1})$$

where R represents  $^{15}\text{N}/^{14}\text{N}$  for  $\delta^{15}\text{N}$ ,  $^{18}\text{O}/^{16}\text{O}$  for  $\delta^{18}\text{O}$ ,  $^2\text{H}/^1\text{H}$  for  $\delta^2\text{H}$ ,  $^{34}\text{S}/^{32}\text{S}$  for  $\delta^{34}\text{S}$  in samples ( $R_{\text{sample}}$ ) and standards ( $R_{\text{std}}$ ) (Kendall et al., 2008).

### 2.2.3 Interpretation techniques

Statistical analyses were performed with the software SPSS 25.0 (IBM, 2017). Historical chemical data from the BA, MMA, and ST were obtained for 2006 and 2012 (Mora et al., 2017). Fifteen sampling points from different campaigns (2006, 2012, 2017) were compared using a Kruskal-Wallis test to elucidate the different parameters' trends.

A hierarchical cluster analysis (HCA) was applied to identify groups that demonstrate similar water chemistry and isotopic ratios. The HCA was performed using 24 variables (temperature, pH, electrical conductivity, oxidation-reduction potential, total dissolved solids, dissolved oxygen,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{HCO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{F}^-$ ,  $\text{B}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^2\text{H}_{\text{H}_2\text{O}}$ ,  $\delta^{18}\text{O}_{\text{SO}_4}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{34}\text{S}_{\text{SO}_4}$ ) employing the average linkage rule of Ward's method. Once the groups were identified, the nonparametric Kruskal-Wallis test was used to establish significant differences between chemical and isotopic datasets among the different groups generated by the HCA. A principal component analysis (PCA) was implemented after the HCA to explain the possible contributors to the total chemical variance controlled by different processes defined by one or more natural/anthropogenic factors. The varimax normalized rotation method was implemented as factor rotation to significantly distribute weights with geochemical data (Charizopoulos et al., 2018; Das et al., 2018; Tiwari et al., 2019). The Kaiser-Meyer-Olkin (KMO) and Bartlett's tests were used to verify the PCA's adequacy, with KMO values of more than 0.7 and Bartlett's significance values lower than 0.05 (IBM, 2017; Meghdadi and Javar, 2018a).

Halides ( $\text{Br}^-$ ,  $\text{Cl}^-$ , and  $\text{I}^-$ ) were used to identify potential pollution sources in the solutes. These elements have a conservative nature, resulting in the minimum amount of interactions with the groundwater flow and subsoil (Panno et al., 2006; Pastén-Zapata et al., 2014). These techniques have been adapted from several previous studies which used the relations  $\text{Cl}^-/\text{Br}^-$  vs.  $\text{Cl}^-$  (Alcalá and Custodio, 2008; Katz et al., 2011; Khazaei and Milne-Home, 2017; McArthur et al., 2012; Panno et al., 2006; Whaley-Martin et al., 2017),  $\text{I}^-/\text{Na}^+$  vs.  $\text{Br}^-$  (Panno et al., 2006; Pastén-Zapata et al., 2014),  $\text{B}^-/\text{Cl}^-$  vs.  $\text{Br}^-/\text{Cl}^-$  (Awaleh et al., 2017; Vengosh, 2014), and  $\text{NO}_3^-/\text{Cl}^-$  vs.  $\text{Cl}^-$  (Lu et al., 2015; Yue et al., 2017; Zeng and Wu, 2014) in combination with diverse end-members to differentiate pollution sources besides mixing and transformation processes.

To estimate the relative contribution of different nitrate and sulfate sources in water samples, the Bayesian isotope mixing model MixSIAR (Stock and Semmens, 2016) was employed. MixSIAR is a combination of models integrated by IsoSource (Phillips and Gregg, 2003), MixSir (Moore and Semmens, 2008), SIAR (Parnell et al., 2010), IsotopeR (Hopkins and Ferguson, 2012), FRUITS (Fernandes et al., 2014) and others. It has been used to assess the contributions of pollution sources such as  $\text{NO}_3^-$  (Griffiths et al., 2016; M. Zhang et al., 2018), heavy metals (Kong et al., 2018; Longman et al., 2018), and sediments (Blake et al., 2018; Dang et al., 2018; Dutton et al., 2019; Liu et al., 2017; Smith et al., 2018; Upadhayay et al., 2018). The authors are not aware of a previous study that assesses the contribution of sources of  $\text{SO}_4$  using these techniques. The mixing model for a set of  $N$  mixture measurements with  $j$  isotopes and  $k$  sources is described by the following equations (Parnell et al., 2010):

$$X_{ij} = \sum_{k=1}^k p_k (S_{jk} + C_{jk}) + \varepsilon_{ij} \quad (\text{Eq. 2.2})$$

$$S_{jk} \sim N(\mu_{jk}, \omega_{jk}^2) \quad (\text{Eq. 2.3})$$

$$C_{jk} \sim N(\lambda_{jk}, \tau_{jk}^2) \quad (\text{Eq. 2.4})$$

$$\varepsilon_{ij} \sim N(0, \sigma_j^2) \quad (\text{Eq. 2.5})$$

Where  $X_{ij}$  represents the isotope value  $j$  of the mixture  $i$ , in which  $i = 1, 2, 3, \dots, N$  and  $j = 1, 2, 3, \dots, J$ ;  $S_{jk}$  indicate the source value  $k$  of isotope  $j$  ( $k = 1, 2, 3, \dots, K$ ), which is normally distributed with mean  $\mu_{jk}$  and standard deviation  $\omega_{jk}$ ;  $p_k$  is the proportional contribution of source  $k$ , which is estimated by the MixSiar model;  $C_{jk}$  describes the isotope fractionation factor of isotope  $j$  on source  $k$ , which follow a normal distribution with mean  $\lambda_{jk}$  and standard deviation  $\tau_{jk}$ ; and  $\varepsilon_{ij}$  is the residual error representing the additional unquantified variation between individual mixtures, which follows a normal distribution with mean zero and standard deviation  $\sigma_j$ . More detailed information on the MixSiar model can be found in Stock et al. (2018). In this study, the mean values ( $\mu_{jk}$ ) and standard deviations ( $\omega_{jk}$ ) of nitrate, sulfate, and oxygen isotopes associated with different end-members were obtained from previous studies.

## 2.3 Results

### 2.3.1 Spatial and temporal trends of groundwater chemistry

To evaluate groundwater chemistry changes over time, the Kruskal-Wallis test (K–W) was applied in three different zones: MMA aquifer, Buenos Aires wellfield, and Santiago system. The test evaluated if there are significant differences (p-value < 0.05) between the years 2006, 2012, and 2017 (**Table 2.1**).

The results show no significant differences in temperature, pH,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{NO}_3^-$ , and  $\text{HCO}_3^-$  for the Buenos Aires wellfield; nevertheless, Cl and  $\text{SO}_4$  concentrations increase two-fold between 2012 and 2017. For the MMA aquifer, there are no significant differences in any of the parameters over time, except for reduced  $\text{K}^+$  concentrations in 2017. The Santiago System shows no significant differences in any parameter. The values of physicochemical and isotopic parameters of 2017 are shown in **Table A1.1** of **Appendix 1**. According to their statistical similarities and geographic correspondence, samples were classified into five groups to understand local geochemical trends (**Fig. 2.2**). The obtained clusters were spatially defined as follow: Group 1 comprises samples collected from the Buenos Aires wellfield and La Estanzuela spring; Group 2 represents wells located in Mina wellfield; Group 3, 4, and 5 are all located in the MMA aquifer and represent samples in the recharge area, transition zone and discharge area of this aquifer, respectively. **Table 2.2** shows the statistical summary of physicochemical parameters and isotopic ratios of each group.

Across all five groups, the average temperature varies substantially between 22.9 and 30.4°C, whereas the average pH ranges over a narrow interval of near-neutral values from 7.0 to 7.4. Across all groups, anion concentrations decreased in the order:  $\text{HCO}_3^- > \text{SO}_4^{2-} > \text{Cl}^- > \text{NO}_3^-$ . In contrast, cation concentrations decreased in the order:  $\text{Ca}^{2+} > \text{Mg}^{2+} > \text{Na}^+ > \text{K}^+$  for groups 1 and 3; and  $\text{Ca}^{2+} > \text{Na}^+ > \text{Mg}^{2+} > \text{K}^+$  for groups 2, 4 and 5. The synthetic parameters ( $\text{HCO}_3^- - (\text{SO}_4^{2-} + \text{Cl}^-)$ ) and  $((\text{Ca}^{2+} + \text{Mg}^{2+}) - (\text{Na}^+ + \text{K}^+))$  were plotted against each other as a scatter plot (Chadha, 1999) to evaluate the hydrogeochemical processes that control groundwater chemistry (**Fig. 2.3a**).

**Table 2.1.** Temporal comparison of physicochemical parameters of groundwater samples in different areas of the Monterrey valley. Mina wellfield is not included because this zone was not considered in the 2006 and 2012 sampling campaign. Note: K–W indicates the significance level (p) of the Kruskal–Wallis test with the gray shaded areas indicating a significant difference across the three sampling years; BA = Buenos Aires, MMA = Monterrey Metropolitan Aquifer, ST = Santiago System.

| Zone | Year | n  | T (°C)     | K-W  | pH          | K-W   | Ca (mg/L)              | K-W   | Mg (mg/L)               | K-W  | Na (mg/L)              | K-W  |
|------|------|----|------------|------|-------------|-------|------------------------|-------|-------------------------|------|------------------------|------|
|      | 2006 | 5  | 22.20±1.26 | 0.98 | 7.46±0.06   | 0.93  | 71.74±1.29             | 0.93  | 13.08±3.49              | 0.85 | 3.67±1.51              | 0.91 |

This plot suggests that Groups 1, 3, and 4 are recharge waters of the Ca–Mg–HCO<sub>3</sub> type, and groups 2 and 5 are more chemically evolved and controlled by reverse ion exchange processes, which lowered the Na concentrations in pore waters even more to produce waters of the Ca–Mg–Cl type. Na in the solution is exchanged for Ca on the clay surfaces in the cases of reverse ion exchange. Inverse ion exchange is typical where solutes with high Na<sup>+</sup> concentrations mix with freshwater, such as in coastal areas with saline intrusion (Mahlknecht et al., 2017; Tamez-Meléndez et al., 2016). In such settings, seawater Na<sup>+</sup> replaces continental Ca<sup>2+</sup> (and Sr<sup>2+</sup>) in the aquifer clay surfaces. In this study, Na<sup>+</sup> concentration increments are possibly due to sewage infiltration since group 5 represents waters in the urbanized discharge area, possibly promoting inverse exchange processes (Thivya et al., 2014). Samples from group 2 exhibit an increased Na content from the weathering of silicate minerals in the Mina wellfield.

**Fig. 2.2.** Dendrogram derived with HCA using the log-transformed and standardized (z-score) water chemistry and isotopic ratios dataset for the 2017 sampling campaign. A dashed horizontal line (phenon line) is used to define five groups of water samples.

The positive correlation between TDS and  $(\text{NO}_3^- + \text{Cl}^-)/\text{HCO}_3^-$  (**Fig. 2.3b**) confirms that water chemistry is heavily influenced by anthropogenic activities (Jalali, 2009; Xiao et al., 2017). Geothermal waters can carry high  $\text{Cl}^-$  concentrations; however, there is no evidence of geothermal waters in the study area. Using this reasoning, group 5 is the most impacted by excess  $\text{Cl}^-$  and  $\text{NO}_3^-$ , likely coming from vertical infiltration through the urban landscape.

**Table 2.2.** Statistical summary of physicochemical parameters and isotopic ratios according to groups. For the values of individual samples, see **Table A1.1** of **Appendix 1**. Note: n denotes the number of samples, and SD denotes standard deviation.

### 2.3.2 Correlation between hydrochemical parameters and pollution sources

As indicated by the Shapiro-Wilks test, a logarithmic transformation was applied to normalize all variables except  $\text{Mg}^{2+}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ , and  $\delta^{18}\text{O}_{\text{SO}_4}$ . Five principal components were identified using PCA, in which the first three explain 65.8% of the total variance. The loadings of the varimax rotated components are shown in **Table 2.3**. The KMO and Bartlett's sphericity test value was 0.79, and the Chi-square value resulted in 1395.43 ( $p$ -value < 0.05), demonstrating an accurate reduction of the hydrochemical data in terms of dimension.

**Table 2.3.** Loadings for each parameter on each new principal component (PC) resulting from the varimax rotation with Kaiser Normalization. The total variance explained by each PC is stated. Bold values indicate parameters that are highly correlated to a given PC (>0.6).

| % of variance                    | 33.59         | 16.20        | 15.55         | 13.64        | 7.03         |
| Cumulative %                     | 33.59         | 49.79        | 65.34         | 78.98        | 86.01        |

The first component (PC1) explains 33.59% of the total variance and broadly describes water-rock interaction processes, namely the dissolution of carbonates and evaporites being responsible for most of the salinity in groundwater of the study area. Nitrate and sulfate concentrations, as well as nitrate isotope ratios, are also correlated with this component. A similar trend was observed in a neighbor aquifer (Pastén-Zapata et al., 2014; Ledesma et al. 2015), where nitrate was found to be originated mostly from sewage leakage and application of manure. However, in this study area, the application of manure is not a common practice. The second component (PC2) explains 16.20% of the variance and relates water isotopes with  $\delta^{34}\text{S}_{\text{SO}_4}$  isotope. It is remarkable that  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ , and  $\text{Cl}^-$  are also positive but less significantly related to this component. Thus, this component could indicate the different origins of groundwater at different altitudes providing distinct signatures. The third component (PC3) represents 15.55% of the variance and describes the long-term water-rock interaction process, evidenced by a strong relationship between F<sup>-</sup> and temperature (Chae et al., 2007; Morales-Arredondo et al., 2018; Singaraja et al., 2018), as

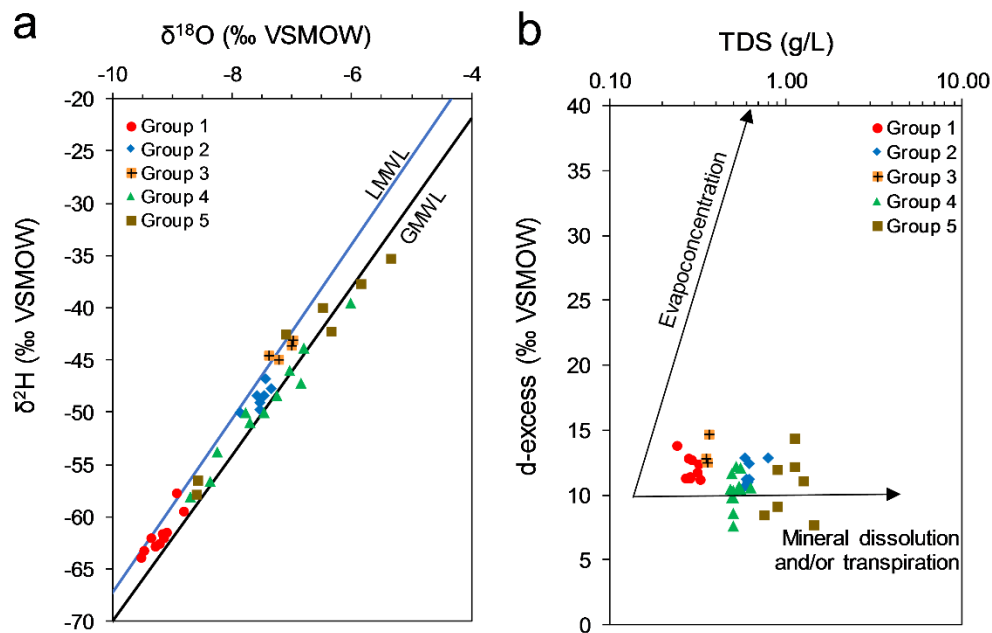

well as a significant inverse relationship between  $\delta^{18}\text{O}_{\text{NO}_3^-}/\delta^{18}\text{O}_{\text{SO}_4^{2-}}$  and dissolved oxygen, suggesting denitrification processes and sulfate reduction (Li et al., 2019). This component appears to be related to processes that mitigate nitrate and sulfate contamination. The fourth component (PC4) contributes 13.64% to the variance and is related mainly to the mobility of  $\text{B}^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$  in groundwater. These elements are positively correlated with  $\text{NO}_3^-$  concentration, which likely indicates anthropogenic contamination from industrialized and urban areas. The fifth component (PC5) depicts a minor proportion of variance (7.03%) and relates the alkali metal  $\text{K}^+$  with redox condition (ORP). This component is possibly related to mobilization of  $\text{K}^+$  through grass degradation and leaching processes, since other sources such as the dissolution of  $\text{K}$ -silicate minerals or evaporites would not have a relevant influence in the redox potential. Unfortunately, commonly measured redox-sensitive elements beyond  $\text{DO}$ ,  $\text{NO}_3^-$ , and  $\text{SO}_4^{2-}$ , which could provide further insight into this component (e.g.,  $\text{NH}_4^+$ ,  $\text{Fe(II)/Fe(III)}$ ,  $\text{Mn(II)}$ ,  $\text{H}_2\text{S}$ ) were not measured (McMahon and Chapelle, 2008).

An examination of the PCA confirms that most groundwater processes can be ascribed to carbonates and evaporites' dissolution. This is evidenced by the strong correlation between  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{HCO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ , and salinity (TDS). These water-rock interactions are accompanied by nitrate pollution derived from urbanization. Nitrate concentrations in the study area are likely generated from organic processes in soils, leakage of sewage lines and wastewater treatment plants, drainage from barnyards, septic tanks, and cesspools, leaching from the use of inorganic and organic fertilizers, and landfills. Regarding sulfate concentrations, there is strong evidence that marine evaporites generate part of the pollution; however, other human-made sources can be inferred due to its high correlation with nitrate. Remarkably, denitrification and sulfate reduction processes are suggested by PCA.

### 2.3.3 Isotopic composition of water

The values of  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  and  $\delta^2\text{H}_{\text{H}_2\text{O}}$  for groundwater in the study area ranged from  $-9.5$  to  $-5.4\text{‰}$  and from  $-63.9$  to  $-36.0\text{‰}$ , respectively (**Fig. 2.4a**). The samples plot between the global meteoric water line (GMWL; Rozanski et al., 1993) and the local meteoric water line for the Sierra Madre Oriental (LMWL; Aguilar-Ramírez et al., 2017), which indicates a

meteoric origin of groundwater. As expected, the most depleted (most negative)  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  values occur in the Buenos Aires wellfield, which is at a higher altitude compared to the other two wellfields. Samples from Mina wellfield cluster narrowly in the central part of the graph. In contrast, samples from MMA aquifer have a considerable variation and are the most enriched (least negative). In particular, samples from group 5 wells in northeastern Monterrey's valley floor represent the most enriched samples reflecting the lowest topographic elevation in the study area. Except for groups 2 and 3, a slight evaporation trend is observed.

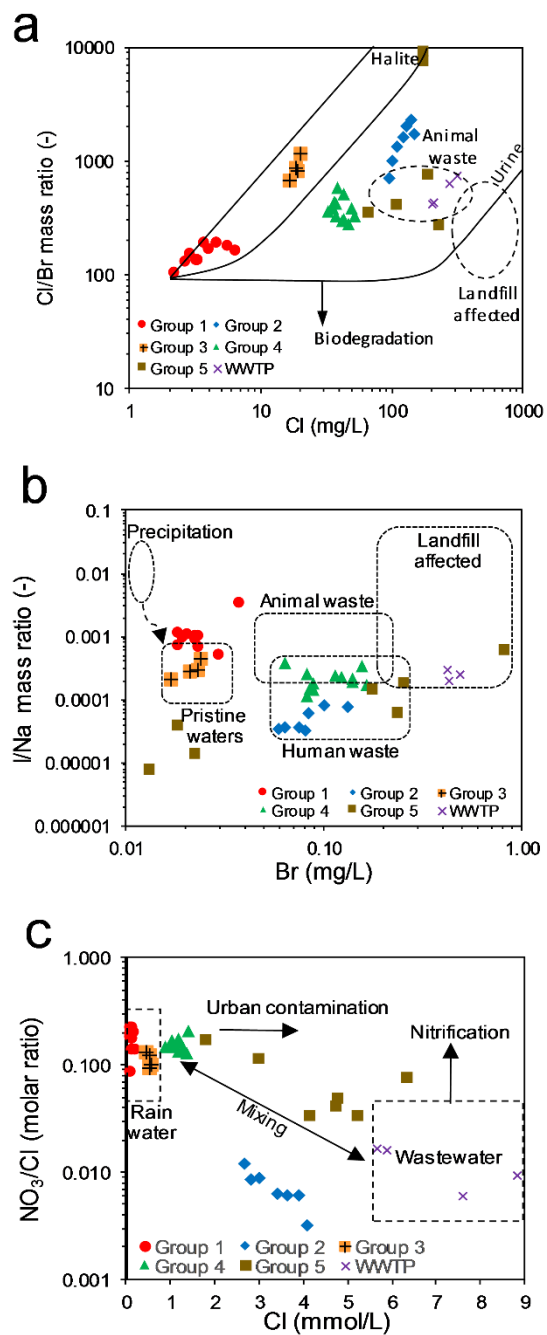

**Fig. 2.4.** (a) Dual isotope plot of  $\delta^2\text{H}\text{-H}_2\text{O}$  and  $\delta^{18}\text{O}\text{-H}_2\text{O}$  of water samples. Note: GMWL is the Global Meteoric Water Line (Rozanski et al., 1993), and LMWL is the Local Meteoric Water Line (Aguilar-Ramírez et al., 2017). (b) Relationship between TDS and d-excess (Huang and Pang, 2012).

The deuterium excess (d-excess) may help identify the contributions of evaporation and/or mineral dissolution to groundwater mineralization. The d-excess is estimated as  $d = ^2\text{H} - 8 \cdot ^{18}\text{O}$ , assuming for precipitation an average of 10‰ ((Dansgaard, 1964). The relationship between d-excess and EC (Huang and Pang, 2012) shown in **Fig. 2.4b** shows that almost all samples are higher than 10‰ and consistent with a mineral dissolution trend. This validates that evaporation is present; however, the influence of evapoconcentration is relatively insignificant.

## 2.4 Discussion

### 2.4.1 Identification of possible pollution sources via halides

Halides ( $\text{Br}^-$ ,  $\text{Cl}^-$ , and  $\text{I}^-$ ) are conservative with minimum interactions with the subsoil; thus, these elements are useful for identifying potential pollution sources (Panno et al., 2006; Pastén-Zapata et al., 2014). Results of this study indicate that Group 1 could be considered as recently infiltrated water derived from rainfall (e.g., dissolution of gaseous  $\text{CO}_2$ ) with minimal impacts from water-rock interactions (**Fig. 2.5a and b**). Likewise, Group 3 is considered recharge water in pristine conditions with specific trends of water-rock interactions (evaporite dissolution such as halite) and mineralization of soil organic matter with nitrate as an end product. Group 2 appears to be affected by sewage from untreated wastewater and/or septic tanks and landfills in Mina municipality. It is notable that the  $\text{NO}_3^-$  to  $\text{Cl}^-$  is relatively low (**Fig. 2.5c**). Group 4 and 5 falls close to or in the range of water affected by human sewage and leaching of landfills and dumps, which agrees with their location in the metropolitan area (**Fig. 2.5**).

**Fig. 2.5.** (a) Relationship between Cl<sup>-</sup>/Br<sup>-</sup> mass ratio and Cl<sup>-</sup> for identifying sources (adapted from Pastén-Zapata et al., 2014); (b) Relationship between I<sup>-</sup>/Na<sup>+</sup> mass ratio and Br<sup>-</sup>; (c) Relationship between NO<sub>3</sub><sup>-</sup>/Cl<sup>-</sup> molar ratio and Cl<sup>-</sup>.

#### 2.4.2 Nitrate sources and attenuation processes

Typical nitrogen transformations (nitrification or denitrification) occur primarily in shallow aquifers. Nitrification is the oxidation of  $\text{NH}_4^-$  to  $\text{NO}_3^-$  and is mediated by bacteria that derive metabolic energy (Kendall, 1998). Denitrification reduces  $\text{NO}_3^-$  to  $\text{N}_2$ ,  $\text{N}_2\text{O}$ , or  $\text{NO}$ , which generally occurs under anaerobic environments (Brandes and Devol, 1997; Koba et al., 1997). In this study,  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  values varied from +2.0 to +14.8‰ and from -0.3 to +9.9‰, respectively. Different nitrate sources were identified for the water samples of the study area using the dual isotopic approach (**Fig. 2.6a**). The isotopic signatures of  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  of sampled water, combined with the different potential  $\text{NO}_3^-$  sources, illustrate that soil organic N and manure/sewage sources were the two primary nitrate sources. Samples from groups 1, 2, and 3 were within the compositional field of soil organic N. The origin of  $\text{NO}_3^-$  for these samples could be related to natural soil sources, which is congruent with their location in recharge areas with limited anthropogenic impact (shrubland, dispersed housings). Samples from Group 2 (Mina well field) exhibit a denitrification process identified by a ratio trend between the range from 1:1.3 to 1:2.1 (Aravena and Robertson, 1998; Minet et al., 2012), resulting in an enrichment of the isotopic composition of  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$ . This may explain the reduced  $\text{NO}_3^-$  vs.  $\text{Cl}^-$  ratio for Group 2 in **Fig. 2.5c**.

On the other hand, samples from Groups 4 and 5 fell into the compositional field of manure/sewage, consistent with the land use of their location (mostly urbanized and partly agricultural land use towards northeast). These two groups also evidence a denitrification process.

The Eh values of the sample waters range from 279 to 443 mV, while dissolved oxygen content varies from 3.2 to 8.1 mg/L. This suggests oxic conditions for most of the studied wells, which would favor nitrification processes. The  $\delta^{18}\text{O}_{\text{NO}_3}$  produced during the nitrification of  $\text{NH}_4^-$  is described as two-thirds of oxygen from soil water and one-third from atmospheric oxygen (Andersson and Hooper, 1983), as expressed in the following:

**Fig. 6.** (a) Dual isotope plot of  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  of dissolved  $\text{NO}_3$  in water samples collected in the study area. The isotopic composition of the primary  $\text{NO}_3$  sources considered are ammonium fertilizers, nitrate fertilizers, soil N, and manure or sewage (Kendall et al., 2008; Puig et al., 2017; Vitòria et al., 2004; Xue et al., 2009); (b)  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  vs.  $\delta^{18}\text{O}_{\text{NO}_3}$  with predicted theoretical trends under different conditions: (1) exchange with  $\text{O}_2$ , (2) nitrification, and (3) exchange with  $\text{H}_2\text{O}$ .

$$\delta^{18}\text{O}_{\text{NO}_3} = 2/3 \cdot \delta^{18}\text{O}_{\text{H}_2\text{O}} + 1/3 \cdot \delta^{18}\text{O}_{\text{O}_2} \quad (\text{Eq. 2.6})$$

Where  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  represents the range of observed ratios ( $-9.5$  to  $-5.4\text{‰}$ ) and  $\delta^{18}\text{O}_{\text{O}_2}$  the theoretical atmospheric  $\text{O}_2$  ( $+23.5\text{‰}$ ) (Xue et al., 2009), the solid gray area in **Fig. 2.6b** represents theoretical values of  $\delta^{18}\text{O}_{\text{NO}_3}$  formed from microbial nitrification, confirming this process in most samples, except for Group 2, where all of the isotopic signatures of  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  were larger than theoretically expected, confirming nitrate attenuation processes (denitrification) (Rivett et al., 2008).

### 2.4.3 Pollution sources and attenuation processes of sulfate

The  $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$  signatures of samples from the study area show compositional ranges from +1.03 to +12.16‰, and from +5.79 to +12.12‰, respectively. Four sources can be related to  $\text{SO}_4^{2-}$ , according to **Fig. 2.7a**: atmospheric deposition from  $\text{SO}_2$  emissions, the influence of soil-derived  $\text{SO}_4$ , sewage, and marine evaporites.

**Fig. 2.7.** (a) Dual-isotope plot of  $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$  in water samples collected in the study area. The isotopic composition of the primary  $\text{SO}_4$  sources is represented by atmospheric deposition, soil sulfate, sewage and marine evaporites (Pittalis et al., 2018; Puig et al., 2017; Vitòria et al., 2004); (b)  $\delta^{34}\text{S}_{\text{SO}_4}$  vs.  $\text{SO}_4/\text{Cl}$  ratio in water samples collected in the study area.

Samples from Groups 1, 3 and 4 plot almost all within the atmospheric deposition range, while samples from Group 5 lie between atmospheric deposition and sewage. For most samples of Group 2, it was not possible to identify the source of sulfate due to an overlapping of source fields (i.e., marine deposits, sewage) and sulfate reduction processes identified by

the typical ratio trends between 1:4 and 1:2.5 (Mizutani and Rafter, 1973) (**Fig. 2.7a**). The following equation describes this process:

Furthermore, in all samples  $\delta^{34}\text{S}_{\text{SO}_4}$  decreases with increasing  $\text{SO}_4/\text{Cl}$  ratio, except for Group 1 (**Fig. 2.7b**), suggesting that isotopically light  $\text{SO}_4^{2-}$  was removed and the residual  $\text{SO}_4$  became enriched in  $^{34}\text{S}$  and  $^{18}\text{O}$  during sulfate reduction in Groups 2, 3, 4, and 5 (Pittalis et al., 2018). For Group 1, an inverse trend is observed with smaller initial sulfate isotope values and larger  $\text{SO}_4^{2-}/\text{Cl}^-$  ratios than the rest. This can be related to an initial  $\text{SO}_4^{2-}$  pool, which agrees with the limestone-gypsum geology of the Buenos Aires wellfield and a subsequent mixture with sulfate from atmospheric deposition (Guo et al., 2015; Mora et al., 2017).

The dual-isotope diagram of  $\delta^{15}\text{N}_{\text{NO}_3}$  vs.  $\delta^{34}\text{S}_{\text{SO}_4}$  further constrains the variety of sources responsible for each of these contaminants even within the same aquifer (**Fig. 2.8**). It confirms that the primary sources of pollution in the sites close to recharge areas (Groups 1, 2, and 3) are atmospheric deposition and mineralization of soil organic matter. In contrast, an additional source, the infiltration of sewage leaks, was identified for samples located in the urban area (Group 4 and 5). This is generally congruent with the findings for nitrate in the previous section.

**Fig. 2.8.** Dual isotope plot of  $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{15}\text{N}_{\text{NO}_3}$  in water samples collected in the study area. The isotopic composition of the primary pollution sources is represented by atmospheric deposition, soil, sewage, and manure (Otero et al., 2009; Puig et al., 2017).

#### 2.4.4 Apportionment of nitrate and sulfate using a Bayesian isotope mixing model

A Bayesian mixing model (MixSIAR) was developed to estimate the proportional contributions of nitrate from the three identified potential sources: atmospheric deposition (AD), soil organic nitrogen (SON), and manure and sewage (M&S). Similarly, a mixing model was developed to estimate the contributions of sulfate from the four identified potential sources: atmospheric deposition (AD), soil sulfate (SS), manure and sewage (M&S), and marine evaporites (ME)). The mean and standard deviation of the isotopic composition used in the MixSIAR for the different pollution sources was estimated from a local end-member and literature (**Table A1.2 of Appendix 1**) and is shown in **Table 2.4**.

**Table 2.4.** Summary of  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ,  $\delta^{34}\text{S}_{\text{SO}_4}$ , and  $\delta^{18}\text{O}_{\text{SO}_4}$  values, from various probable end-members used in MixSIAR model (extended results in **Table A1.2 of Appendix 1**).

| Source                 | $\delta^{15}\text{N}-\text{NO}_3$ | $\delta^{18}\text{O}-\text{NO}_3$ | $\delta^{34}\text{S}-\text{SO}_4$ | $\delta^{18}\text{O}-\text{SO}_4$ |
|------------------------|-----------------------------------|-----------------------------------|-----------------------------------|-----------------------------------|
|                        | Mean $\pm$ SD                     | Mean $\pm$ SD                     | Mean $\pm$ SD                     | Mean $\pm$ SD                     |
| Atmospheric deposition | 0.89 $\pm$ 2.12                   | 57.59 $\pm$ 12.47                 | 5.47 $\pm$ 1.39                   | 11.65 $\pm$ 1.54                  |
| Soil organic nitrogen  | 3.98 $\pm$ 1.95                   | 2.51 $\pm$ 1.41                   | -                                 | -                                 |
| Soil sulfate           | -                                 | -                                 | 2.74 $\pm$ 1.44                   | 3.66 $\pm$ 2.78                   |
| Marine evaporites      | -                                 | -                                 | 16.02 $\pm$ 3.14                  | 13.32 $\pm$ 4.27                  |
| Sewage/Manure          | 13.25 $\pm$ 3.24                  | 4.87 $\pm$ 1.87                   | 5.98 $\pm$ 1.98                   | 6.86 $\pm$ 1.60                   |

The results reveal that the nitrate source contribution in the study area generally followed SON > M&S > AD, with mean and standard deviation values of 60.6  $\pm$  12.4%, 37.8  $\pm$  12.5%, and 1.6  $\pm$  1.2%, respectively, as illustrated in **Fig. 2.9a,c**. Specifically, groups 1, 2, and 3 showed similar patterns, with the highest shares derived from SON with 96.8  $\pm$  4.2%, 68.4  $\pm$  15.9%, and 78.4  $\pm$  11.3%, respectively. In contrast, for groups 4 and 5, the dominant nitrate source was M&S (54.5  $\pm$  18.6%, and 84.5  $\pm$  12.5%, respectively). Atmospheric deposition contributed little nitrate to the groundwater. This agrees with studies performed in other areas (Li et al., 2019; Matiatos, 2016; Xue et al., 2012; Yue et al., 2017). These results are generally consistent with the qualitative analysis of the dual isotopic approach (**Fig. 2.6a**).

**Fig. 2.9.** (a) Average proportional contributions of three potential nitrate sources estimated by MixSIAR model for the different groups as a percentage; (b) average proportional contributions of four potential sulfate sources as percentage estimated by MixSIAR model for the different groups as a percentage; (c) average contribution of potential nitrate sources as concentration (mg/L); (d) average contribution of sulfate sources as concentration (mg/L).

Sulfate source contribution generally followed M&S > AD > ME > SS with mean and standard deviation values of  $40.6 \pm 18\%$ ,  $24.9 \pm 10\%$ ,  $18.4 \pm 5.5\%$ , and  $16.1 \pm 11.9\%$ , respectively. The main sulfate source was M&S for group 1 ( $38.9 \pm 29.8\%$ ), group 3 ( $43.4 \pm 22.6\%$ ), group 4 ( $57.0 \pm 22.7\%$ ), and 5 ( $41.1 \pm 21.6\%$ ), while for group 2 it was marine evaporites ( $38.7 \pm 11.7\%$ ) (**Fig. 2.9b and c**). This mixing model exercise helped to discern the contribution of distinct sulfate sources whose isotopic compositional ranges show overlaps in **Fig. 2.7a**.

The summary of the results employing this multi-tracer approach combined with the Bayesian isotope mixing model is shown in **Table A1.3** of **Appendix 1**. In general, the isotope mixing model results using the Bayesian approach were consistent with interpretations based on the hydrochemical and isotopic data. However, one limitation of this approach is that the isotopic ranges of sources were derived from literature. Further

investigations to constrain local end-members' isotopic and chemical composition are necessary to reduce the results' variance and uncertainty.

#### 2.4.5 Recommendations for reducing nitrate and sulfate pollution and future research

Based on the results of this study, soil organic nitrogen and sewage were the most critical nitrate and sulfate sources in groundwater. While there exist natural denitrification processes in the study area, these are locally limited. Monterrey's rapid economic and industrial growth during the last 100 years resulted in reduced or lost ecological processes of the urban mosaic. Specifically, the urban Santa Catarina river and its tributaries have been degraded and extremely “flashy” today, exhibiting a rapid increase in flow following storms. The increase in imperviousness, changes to the hydrological flow path, and the increase of nitrate sources in the urban landscape have all contributed to a decrease in water quality. The biogeochemical implications of the engineered changes are that riparian zones with their expected high levels of denitrification due to their vegetation composition, microbial populations, soil conditions, and hydrological regimes are faulty because they are altered and disconnected from urban streams, followed by a transition from anaerobic to aerobic conditions reducing the potential of denitrification.

Designs that re-establish ecological processes (restoration) can create hotspots of denitrification where the stream–riparian interface has been modified to facilitate the interaction of stream water with the riparian zone. Infrastructure can be added, which serves as nitrate sink, as in detention basins, or removed from daylighting buried urban streams, or modified as in bioretention ponds and level spreaders to mimic natural structures and ecological processes better. The introduction of green roofs or permeable surfaces to enhance water infiltration farther upslope in the hydrological flow paths are other strategies that increase the capacity of mitigation of nitrate.

Monterrey has a special status in Latin America regarding access to drinking water and sanitation. The population enjoys universal access to water distribution and sewerage. This means that practically all generated water and wastewater is treated in treatment facilities. The sewage system has been built starting in the early 1900s and expanded over time. It operates as a combined system, simultaneously collecting surface runoff and sewage water

in a shared system. Hence, the existence of reaches of old pipes and tunnels combined with limited preventive maintenance over prolonged periods and overflows during the rainy seasons have contributed to groundwater pollution (Olds et al., 2018; Selvakumar et al., 2004), especially considering that the groundwater table of MMA is located only about 7–20 m below ground level.

In this sense, it is recommended that the water and sanitation utility pays special attention to the oldest parts of the city/sewage system, which coincide geographically with shallow unconfined aquifer conditions (sample groups 3 and 4). In these areas, exfiltration of the sewage from damaged reaches is a common problem and needs rehabilitation measures. These rehabilitation projects will take many years to complete.

On the other hand, the discharge zone of MMA is strongly industrialized (group 5). According to Mexican law, industries are forced to comply with environmental standards when discharging the generated wastewater into water bodies. Thus, it is imminent to monitor industrial discharges in terms of water quality and avoid illegal dumping to the environment.

Furthermore, a revision of the sanitation plan is required, including promoting decentralized approaches in peri-urban and rural areas. For example, Mina (group 2) and Buenos Aires (group 1) are appropriate candidates for this kind of solution. They may maintain low nitrate and sulfate concentrations by reducing the infiltration of untreated wastewater from septic tanks and cesspools to the shallow aquifer and preserve the actual situation of water quality (Clemens et al., 2020; Oakley et al., 2010).

Finally, it is essential to create a long-term groundwater monitoring network of nitrate and sulfate in the entire aquifer system to control the evolution of the contamination in time and space. Future research efforts should be developed towards evaluating seasonal changes of pollution and the use of microorganisms and micropollutants as co-tracers for a more robust conceptualization of contamination paths and evaluation of mitigation measures in a complex groundwater system.

## 2.5 Conclusion

A multi-tracer study using chemical and isotopic fingerprints combined with a probability mixing model was conducted to understand the origin and source contribution of nitrate and sulfate pollution in groundwater of the urbanized valley of Monterrey. Nitrate pollution was mainly derived from sewage leaks in the urban area (37.8%). In contrast, soil organic nitrogen was responsible for nitrate concentration in the recharge areas (81.2%). Similarly, sulfate pollution in the city was caused by sewage infiltration (45.1%) in the groundwater and atmospheric deposition (24.9%) due to anthropogenic emissions. In recharge areas, sulfates result from the interaction between water and marine evaporites (38.7%).

The hydrochemical data suggests that groundwater of the study area is dominated by a Ca–Mg–HCO<sub>3</sub> water type in the topographically elevated, non-urbanized areas (Buenos Aires) and a Ca–Mg–Cl water type in transition and discharge areas of the Monterrey metropolitan area and Mina (northwest of Monterrey). The latter chemistry type and locations suggest mixing between recharge waters and sewage leaks and possibly inverse cation exchange processes.

Stable water isotopes suggest that water in the study area has a meteoric origin with some evaporation effects in the transition areas. However, evapoconcentration is insignificant compared to mineral dissolution. The multivariate analysis confirms that carbonate and evaporite dissolution drives groundwater mineralization.

The halide concentrations evaluation revealed that samples close to recharge areas in Buenos Aires indicate recently recharged meteoric water un-impacted by anthropogenic contaminants. These waters represent recent infiltrated water that has experienced water-rock interactions, such as carbonate and halite dissolution, and mineralization of soil organic matter with nitrate as an end product. Along the flow path, these groundwaters mix with sewage leakages and leach from landfills. These processes are likely operating within the Mina wellfield and the transition and discharge zone of MMA aquifer.

The dual-isotope approach confirms that natural contamination by mineralization of soil organic nitrogen and anthropogenic contamination by sewage leakages and leaching from

landfills is the primary nitrate source. Also, it suggests the presence of denitrification processes in the Mina area and the discharge zone of MMA aquifer northeast of the Monterrey area. On the other hand, sulfate contamination originated naturally by the dissolution of marine evaporites such as gypsum, especially in the Buenos Aires area, and from anthropogenically-contaminated from atmospheric deposition from emissions and leakages from sewage in the urbanized area.

Probability mixing models using the Bayesian method confirm that leakage derived from sewage is not the only important pollution source of  $\text{NO}_3$  and  $\text{SO}_4$ , proving that natural sources (nitrogen and sulfate derived from the soil) play also impact groundwater chemistry. Moreover, mixing with different pollution sources could be identified for the urbanized area. However, future investigations should perform a detailed characterization of the isotopic composition ranges of the different local sources to reduce the uncertainty of the probability mixing results.

Monterrey's rapid economic and industrial growth resulted in reduced and lost ecological processes in the urban mosaic and limited sewage system maintenance. Restoration efforts can create natural structures and infrastructure which serve as nitrate and sulfate sink. The continuous rehabilitation of the sewage system in the older urban landscape may reduce exfiltrations to the underlying close groundwater table. Decentralized on-site treatment systems may be promoted in periurban and rural areas as cost-effective solutions to prevent pollution in distant areas. A long-term monitoring network serves to control the pollution and to evaluate mitigation measures.

This methodology is a useful tool that can be successfully applied in catchments for a qualitative and quantitative evaluation of the contribution of different pollution sources in groundwater, providing essential information for water managers.

# Chapter 3: Comarca Lagunera Region Case

This chapter is adapted from the published article

J.A. Torres-Martínez, A. Mora, J. Mahlkecht, L.W. Daesslé, P.A. Cervantes-Avilés, R. Ledesma-Ruiz, 2020. *Estimation of nitrate pollution sources and transformations in groundwater of an intensive livestock-agricultural area (Comarca Lagunera), combining major ions, stable isotopes and MixSIAR model.* **Environmental Pollution**, In Press, 115445. DOI: 10.1016/j.envpol.2020.115445

### 3.1 Introduction

Nitrate ( $\text{NO}_3^-$ ) is a ubiquitous environmental pollutant that occurs naturally and is released by human activities. These activities include the production and use of fertilizers, the combustion of fossil fuels (resulting in atmospheric deposition, hereafter AD), the leakage and discharge of both industrial and domestic sewage systems, and the alteration of natural vegetation with nitrogen (N)-fixing crops (Gutiérrez et al., 2018; Ward et al., 2018). Population growth has led to an increased food demand, which has resulted in the production and disposal of considerable amounts of N in the form of natural (manure) and synthetic fertilizers, especially in places where intensive-farming practices are performed (Tilman et al., 2002). The application of large quantities of fertilizers to meet the N demand of crops, combined with the return flow associated with irrigation, has increased the  $\text{NO}_3^-$  concentrations in the surface water bodies and groundwater of agricultural in particular (Merchán et al., 2020). Therefore, N-fertilizers' indiscriminate use raises significant human and ecological issues due to the resultant excessive  $\text{NO}_3^-$  concentrations in water. This may lead to the degradation of surface waters, groundwater, and coastal or marine ecosystems (Gutiérrez et al., 2018; Mekonnen and Hoekstra, 2015; Nikolenko et al., 2018).

Although it is difficult to distinguish the sources of  $\text{NO}_3^-$  in complex systems, source identification is of primary importance for proposing appropriate management plans in  $\text{NO}_3^-$  vulnerable zones. This relates to potential adverse health effects (Blaisdell et al., 2019) and biota (Camargo et al., 2005) associated with  $\text{NO}_3^-$  pollution. The stable isotopes of  $\text{NO}_3^-$  (i.e.,  $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$ ) have been widely used to differentiate the sources that can account for the total  $\text{NO}_3^-$  concentration in surface water and groundwater. Unfortunately, the use of dual-isotope fingerprints to trace  $\text{NO}_3^-$  sources have not been entirely successful to date due to the possibility of overlapping areas of two or more  $\text{NO}_3^-$  sources, which hampers the distinction among origins (Minet et al., 2017; Xue et al., 2012; Zhu et al., 2019). In addition, the transformation of N in the environment and the use of regional agricultural methods can also preclude the identification of  $\text{NO}_3^-$  sources when the dual-isotope method is used. Both nitrification and denitrification processes lead to a shift in the  $\text{NO}_3^-$  isotopic composition due to the fractionation of stable N and oxygen isotopes (Aravena and Robertson, 1998; Snider et al., 2010). Moreover, the potential sources of  $\text{NO}_3^-$  can display different isotopic values

from one region to another, depending on people's lifestyles and farming practices (Y. Zhang et al., 2018a).

Accordingly, recent studies have mainly focused on identifying the sources of  $\text{NO}_3^-$  by combining dual-isotope  $\text{NO}_3^-$  analysis with other chemicals, biological and/or statistical approaches; for example, halide ratios (Katz et al., 2011; Pastén-Zapata et al., 2014), boron and strontium isotopes (Meghdadi and Javar, 2018b), multivariate statistical methods (Matiatos, 2016; Meghdadi and Javar, 2018a), groundwater bacteria (Meghdadi and Javar, 2018a) and multi-stable isotope approaches (Biddau et al., 2019). Furthermore, some methods have been implemented to develop a reliable way of providing quantitative estimates of the contributions of natural and anthropogenic  $\text{NO}_3^-$  sources to the total  $\text{NO}_3^-$  pool in specific environments. These methods include the use of chemical and mathematical tools such as mass balance calculations (Degnan et al., 2016), end-member mixing analysis (Grimmeisen et al., 2017; Ogrinc et al., 2019), and statistical models including multi-linear regression analysis (Meghdadi and Javar, 2018a) and the Bayesian mixing models (Liu et al., 2018; Matiatos, 2016; Meghdadi and Javar, 2018a; Xue et al., 2012; Y. Zhang et al., 2018a; Zhao et al., 2019).

The Comarca Lagunera Region (CLR) is an economically significant irrigation district in northern Mexico, where livestock and agricultural activities make a significant contribution to the national gross domestic product. The water supplied the CLR originates from both groundwater and surface water sources, although the latter only includes Francisco Zarco Reservoir, which is used for irrigation purposes. Rapid population growth, arid conditions, and prolonged droughts in CLR mean that groundwater has become a crucial resource for public supply, livestock, agricultural, and mining activities. Groundwater is the principal drinking water source for the approximately 1.6 million inhabitants of the CLR, who mainly live in three cities. Hence, the regional water table has dropped rapidly over recent decades, resulting in the over-exploitation of the aquifer system and water quality deterioration, including an increased arsenic (As) concentration in groundwater (Ortega-Guerrero, 2017).

Although some research on the water quality has been undertaken regarding water quality and pollution in the CLR, these have focused mainly on assessing the behavior of As in groundwater (Del Razo et al., 1990; Mejía-González et al., 2014; Ortega-Guerrero, 2017).

Despite CLR being an important area for livestock and agricultural production, there are no known studies that have evaluated the dynamics of  $\text{NO}_3^-$  in groundwater or the effect of groundwater over-exploitation on the  $\text{NO}_3^-$  concentration. Thus, the objectives of this chapter are: 1) to assess the  $\text{NO}_3^-$  concentration in the groundwater of the CLR, 2) to identify the sources and transformation processes of  $\text{NO}_3^-$  in groundwater by using stable isotopes, and 3) to quantify the apportionment of different potential  $\text{NO}_3^-$  pollution sources through the use of a Bayesian isotope mixing model. This chapter will help improve the knowledge about  $\text{NO}_3^-$  source apportionment in complex groundwater environments with multiple diffuse sources.

## **3.2 Materials and methods**

### **3.2.1 Description of the study area**

The CLR (31000 km<sup>2</sup>) is located in the central region of northern Mexico (24°22' to 26°45' N, 102°14' to 104°48' W) in an inter-mountain basin enclosed by the physiographical sub-provinces of Laguna de Mayrán and Bolsón de Mapimí. The regional topography ranges from the highest peaks that reach 3700 m above sea level (a.s.l.) to the valley plains at about ~1050 m a.s.l. The underlying geology of these sub-provinces includes limestone, dolomite, and conglomerates. The basin floor comprises alluvial deposits (depth of 50-500 m), including sand, gravel and conglomerate, lacustrine sediments, and gypsum. The basin is located at the Nazas and Aguanaval rivers' confluence, which are the main surface waterways of the area. However, their main channels run dry as they only receive water during intense rainfall events due to the Lázaro Cárdenas and Francisco Zarco reservoirs, which were built for drinking and irrigation purposes.

The climate in this zone is arid to semi-arid, with a mean annual temperature of 21.3 °C. Temperatures range from 0 to 8 °C during the autumn and winter (November-February), whereas a maximum of 45 °C can occur during the summer (July-August). The average annual rainfall is 250 mm, most of which occurs between June and September. Due to the scarce rainfall and high temperatures during the summer, the surface water availability is low. Thus, the entire region depends on groundwater resources obtained from six administrative aquifer units that comprise the interconnected basin's groundwater system,

namely Principal-Lagunera Region, Vicente Suárez, Villa Juárez, Oriente-Aguanaval, Pedriceña-Velardreña, and Nazas (**Fig. 3.1**).

**Fig. 3.1.** (a) Location of the Comarca Lagunera Region (CLR) in northern Mexico; (b) the administrative delimitation of aquifers; (c) land use/land cover, the locations of the sampled wells, and the main metropolitan area in the CLR, which includes Torreón, Gomez Palacio and Lerdo.

The study area is characterized by intensive agricultural and livestock areas covering 11.6% of the CLR's total area. The principal crops of the region are alfalfa (3.4 million ton/year), corn (2.5 million ton/year), sorghum (745 000 ton/year), wheat (674 000 ton/year), and melon (160 000 ton/year); livestock breeding includes mainly cattle (>400 000 heads of cattle raised for milk production, and > 350 000 for meat production) and poultry (SIAP, 2018a, 2018b). As mentioned, the CLR has a total population of ca. 1.6 million, which is mostly represented by the Laguna metropolitan area, which comprises Torreón, Gómez Palacio, and Lerdo cities (**Fig. 3.1c**), covering ~0.9% of the total area of the CLR. The remaining area of the CLR includes grassland (18.5%), shrubland (68.5%), and mixed forests (0.5%).

Several studies have shown that groundwater in the study area can be strongly affected by salinization as the total dissolved solids concentration has been found to range from 140 to 5100 mg/L (Azpilcueta Pérez et al., 2017; Brouste et al., 1997; Saldarriaga-Noreña et al., 2014). High salinization is mainly due to: (1) the drying up of ancient lakes, which led to the

development of evaporite rocks as a result of climatic factors, (2) the construction of the Lázaro Cárdenas and Francisco Zarco dams on the Nazas River, which blocked water inputs to the river, and (3) the groundwater return flow from irrigation. Moreover, several studies have pointed out that the groundwater flow in the area has reversed from the ancient lakes towards urbanized and agricultural zones due to the continuous abstraction of groundwater for public purposes and irrigation/livestock activities (Brouste et al., 1997; Ortega-Guerrero, 2003; Saldarriaga-Noreña et al., 2014). Overall, we focused our research on the sources and sinks of  $\text{NO}_3^-$  in four of the six aquifer units of the CLR: Principal-Lagunera Region, Villa Juárez, Oriente-Aguanaval, and Nazas. These aquifers are located in urbanized areas or areas where intensive livestock and agriculture activities are performed (**Fig. 3.1**). The hydrogeological characteristics of these aquifers are summarized in **Appendix 2**.

### 3.2.2 Sample collection

By considering the different land-use patterns, the potential pollution sources, and the previous hydrochemical data from the Mexican National Water Agency (Comisión Nacional del Agua - CONAGUA), 53 sampling sites, covering most of the study area, were selected. All samples were taken from production wells that are mainly used for irrigation and municipal water supply. These wells are primarily located in alluvium or limestone at depths typically ranging from 50 to 500 m. In the basin's upper region, the production wells near the Nazas and Aguanaval rivers' paths have construction depths ranging from 75 to 150 m (DOF, 2015). In the intermediate zone that includes the region limited by the metropolitan area, 60 deep wells are ranging from 125 to 500 m deep (García-Salazar and Mora-Flores, 2008), and finally, in the lower part of the basin, the depth of the wells varies from 150 to 300 m (Rivas Sada, 2011). For wells used for municipal drinking water supply, it is mandatory to include a 6 m (minimum) stainless steel casing from the top of the well, whereas there are no restrictions for irrigation wells (CONAGUA, 2019; SEMARNAP, 1997). Consequently, most of the CLR production wells are fully screened to the bottom below the casing.

Samples were collected during November 2018, when there were no rain events. To avoid the collection of stagnated water, boreholes were purged until measurements of pH and electrical conductivity (EC) were stabilized before collecting the groundwater samples. Field

parameters (pH, temperature, oxygen reduction potential (ORP), salinity, and EC) were subsequently determined directly in situ using a pre-calibrated YSI Professional Plus multiparameter meter. After collection, all water samples were filtered through 0.45- $\mu\text{m}$  pore-size acetate cellulose membranes by frontal filtration. Bicarbonate was measured in the filtered water samples in situ by the acid titration method using  $\text{H}_2\text{SO}_4$  (0.02N) until a pH of 4.3. Samples for analyses of anions, cations, and stable nitrate isotopes were collected in triple-rinsed HDPE bottles. Samples for cation analysis were acidified with ultrapure HCl to  $\text{pH} < 2$  to prevent major element precipitation or adsorption during storage. Samples for cation and anion analyses were stored at 4 °C until processing. Samples for  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  analyses were frozen at  $-20^\circ\text{C}$  to avoid variations caused by biological processes. Stable nitrate isotope analysis was carried out a month after the sampling campaign.

### 3.2.3 Analytical procedures

Chemical analyses were performed by Activation Laboratories Ltd. (Canada). Anions were analyzed using ion chromatography (Dionex DX-120), while cations were analyzed using inductively coupled plasma optical emission spectrometry (ICP-OES; Agilent Axial). The charge balance was verified in all samples by considering those with error values of  $< 10\%$  as acceptable.

Isotopic analyses were performed at the Environmental Isotope Laboratory (EIL) of the University of Waterloo in Canada. The  $\delta^2\text{H}_{\text{H}_2\text{O}}$  and  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  analyses followed the methodology described by Berman et al. (2013) using an off-axis integrated cavity output spectroscopy (OA-ICOS) water isotope analyzer (LWIA, Los Gatos Research Inc.). The  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  values were determined following the chemical reduction method (Ti et al., 2018) by first reducing  $\text{NO}_3^-$  to  $\text{NO}_2^-$  via a cadmium catalyst chemically converting to  $\text{N}_2\text{O}$ , before using a trace-gas isotope-ratio mass spectrometer (TG-IRMS; GVI IsoPrime). For quality control purposes, a normalization using two international calibrated standards (USGS 34 and USGS 35) and one internal laboratory standard (EGC 17) were applied. The analytical accuracy was  $\pm 0.3\text{‰}$  for  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\pm 0.8\text{‰}$  for  $\delta^{18}\text{O}_{\text{NO}_3}$ .

All stable isotope results were expressed as delta values by representing the deviations in per mil (‰) from the respective reference standard following **Eq. 3.1**:

$$\delta(\text{‰}) = 1000 \times (R_{\text{sample}}/R_{\text{standard}}) - 1 \quad (\text{Eq. 3.1})$$

where,  $R_{\text{sample}}$  and  $R_{\text{standard}}$  are the measured isotopic ratios ( $^2\text{H}/^1\text{H}$ ,  $^{15}\text{N}/^{14}\text{N}$ , or  $^{18}\text{O}/^{16}\text{O}$ ) for the sample and standard, respectively. The  $^{15}\text{N}/^{14}\text{N}$  ratio in nitrates is reported as  $\delta^{15}\text{N}_{\text{NO}_3}$  with respect to atmospheric  $\text{N}_2$ , whereas  $^2\text{H}/^1\text{H}$  and  $^{18}\text{O}/^{16}\text{O}$  ratios are reported with respect to the Vienna Standard Mean Ocean Water (VSMOW).

### 3.2.4 Data analyses

Multivariate statistical analysis is a common approach used for groundwater classification and provides insights into the relationships among different hydrochemical parameters for a given set of groundwater samples. In this research, two multivariate statistical methods were performed using R software (R Core Team, 2019): a hierarchical cluster analysis (HCA) and a principal component analysis (PCA) in Q and R modes.

The HCA and PCA were applied to the entire dataset, including field parameters (temperature, ORP, pH, dissolved oxygen (DO), TDS and EC), major constituents ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{HCO}_3^-$ ,  $\text{Cl}^-$ ,  $\text{F}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and Si), and minor constituents (Br and I<sup>-</sup>). For the statistical analyses and graphical results, values below the detection limit (DL) were replaced by 0.5 of the DL value. Typically, most chemical parameters distribution does not follow a normal distribution; thus, to avoid spurious correlations, a compositional data technique, namely centered log-ratio (clr) transformation, was applied. This transformation involves dividing each component ( $x$ ) by the geometric mean ( $g(X)$ ) of all variables according to the equation **Eq. 3.2**:

$$\text{clr}(x_i) = \ln \frac{x_i}{g(X)} \quad (\text{Eq. 3.2})$$

Once the data were transformed, an HCA was performed to determine significant groups of water samples via Ward's method. The normality of each resulting group was analyzed using the Shapiro-Wilk test, and the difference of the variables among the groups was compared using an analysis of variance (ANOVA) test at a significance level of  $p < 0.05$ . The non-parametric Kruskal-Wallis test was applied if the normality assumption was not met across

the groups. After conducting the HCA, a PCA was applied to extract variables and infer the main natural or anthropogenic factors controlling each groundwater group (nitrate content).

### 3.2.5 Estimation of contributions from different nitrate pollution sources

The proportional contributions of the different  $\text{NO}_3^-$  pollution sources were assessed using the Bayesian stable isotope mixing model MixSIAR (version 3.0.2) developed in the R environment. A detailed description of the MixSIAR model is described in Stock et al. (2018). Dual-isotopic nitrate values of the groundwater samples and six potential sources (atmospheric deposition (AD), synthetic fertilizers ( $\text{NH}_4^+$  (NHF) and  $\text{NO}_3^-$  (NOF) based fertilizers), soil organic nitrogen (SON), and sewage (S) and manure (M) were included in the model to quantify the fractional contribution of  $\text{NO}_3^-$ . The different end-member isotopic compositions were defined based on previous literature (Fenech et al., 2012; Gutiérrez et al., 2018; Nikolenko et al., 2018; Xue et al., 2009) as follows: AD ( $\delta^{15}\text{N}_{\text{NO}_3}$ :  $0.11 \pm 1.69\text{‰}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ :  $54.97 \pm 7.63\text{‰}$ ); NHF ( $\delta^{15}\text{N}_{\text{NO}_3}$ :  $1.24 \pm 1.44\text{‰}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ :  $3.44 \pm 2.47\text{‰}$ ), NOF ( $\delta^{15}\text{N}_{\text{NO}_3}$ :  $-0.07 \pm 2.85$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ :  $24.12 \pm 3.17\text{‰}$ ), SON ( $\delta^{15}\text{N}_{\text{NO}_3}$ :  $3.26 \pm 1.99\text{‰}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ :  $3.34 \pm 2.04\text{‰}$ ) and M&S ( $\delta^{15}\text{N}_{\text{NO}_3}$ :  $10.14 \pm 4.53\text{‰}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ :  $5.69 \pm 2.91\text{‰}$ ).

## 3.3 Results

### 3.3.1 Water sample groupings and hydrogeochemical characterization

The mean, range, median, and standard deviation (SD) of the physicochemical variables (temperature, ORP, pH, EC) major ions ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{HCO}_3^-$ ,  $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ), and stable isotopes ( $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^2\text{H}_{\text{H}_2\text{O}}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ) of the groundwater samples from the CLR are summarized in **Table 3.1** and provided in full in **Table A2.1** of **Appendix 2**. The detailed results obtained from the HCA are displayed in **Fig.3.2**. According to these results, the water samples were classified into three groups defined by their statistical similarities obtained from the horizontal phenon line with a linkage distance (pairwise distances between observations) above 6.0 in order to understand local geochemical trends (**Fig.3.2**). The clusters were spatially defined as follows: group 1, which comprises the most mineralized/ $\text{NO}_3^-$  polluted water samples that mainly corresponded to groundwater

discharge areas; group 2, which represents wells located in a transition zone; group 3, which denotes samples in the groundwater recharge areas.

There was no significant difference between the depth to the water table across the three groups, which fluctuated between 3.2 and 192.7 m below ground level; however, in terms of administrative units, water table levels from the Principal-Lagunera Region unit were significantly lower ( $p < 0.01$ ) than the rest of the units. The groundwater temperature across the groups varied substantially from 20.70 to 34.40 °C; however, within-group 3 varied from 30 to 34.4 °C, which was significantly higher ( $p < 0.01$ ) than that of both groups 1 and 2. The samples from groups 1 and 2 had near-neutral pH values (6.8-7.9), whereas some of the samples in group 3 had slightly alkaline pH values (mean  $7.9 \pm 0.6$ ) that were significantly higher than those of the other two groups ( $p < 0.001$ ). The redox potential varied from 114.7 to 491.5 mV in all groups and was not significantly different. The DO concentration in group 1 (mean of 4.6 mg/L) was significantly higher ( $p < 0.01$ ) than that in groups 2 and 3, which exhibited means of 2.6 and 3.9 mg/L, respectively.

**Fig. 3.2.** Dendrogram derived from an HCA employing the centered log-ratio transformation of water chemistry and isotopic ratio dataset. Note: A dashed horizontal line (phenon line) is used to define the three groups of water samples. The x-axis denotes the grouping of the different sampling wells.

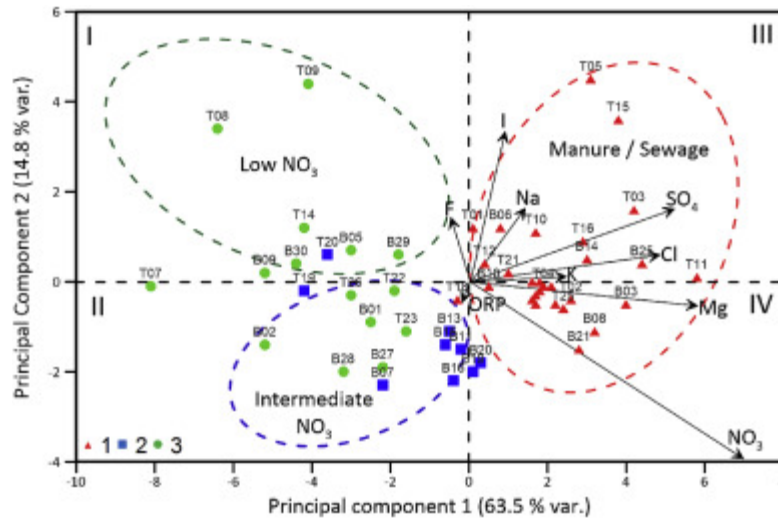

Mean TDS and EC values for group 1 were 1942.9  $\mu\text{S}/\text{cm}$  and 1473.6  $\text{mg}/\text{L}$ , respectively, and mean  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Br}^-$ ,  $\text{I}^-$ , and  $\text{Si}$  concentrations were 203.4  $\text{mg}/\text{L}$ , 70.1  $\text{mg}/\text{L}$ , 671.5  $\text{mg}/\text{L}$ , 949.6  $\mu\text{g}/\text{L}$ , 149.7  $\mu\text{g}/\text{L}$ , and 21.4  $\text{mg}/\text{L}$ , respectively. Overall, these values were significantly higher ( $p < 0.01$ ) than those for groups 2 and 3. Additionally, the  $\text{Mg}^{2+}$ ,  $\text{K}^+$ , and  $\text{HCO}_3^-$  concentrations for groups 1 and 2 were significantly higher than those of group 3 ( $p < 0.05$ ). The mean  $\text{Ca}^{2+}$  and  $\text{NO}_3^-$  concentrations decreased significantly ( $p < 0.05$ ) in the order of group 1 ( $\text{Ca}^{2+}$ : 205.9  $\text{mg}/\text{L}$ ;  $\text{NO}_3^-$ : 20.2  $\text{mg}/\text{L}$ ) > group 2 ( $\text{Ca}^{2+}$ : 83.8  $\text{mg}/\text{L}$ ;  $\text{NO}_3^-$ : 4.27  $\text{mg}/\text{L}$ ) > group 3 ( $\text{Ca}^{2+}$ : 33.4  $\text{mg}/\text{L}$ ;  $\text{NO}_3^-$ : 1.19  $\text{mg}/\text{L}$ ). There was a significant difference between the three groups.

**Table 3.1.** Statistical summary of descriptive statistics for physicochemical parameters and isotopic ratios in the CLR. Note: d: deuterium excess =  $\delta^2\text{H} - 8 \delta^{18}\text{O}$ .

| Group       |        | T (°C)    | ORP (mV)               | pH                     | DO (mg/L)                     | EC ( $\mu\text{S}/\text{cm}$ ) | Ca (mg/L) | Mg (mg/L)                                  | Na (mg/L)                               | K (mg/L) | HCO <sub>3</sub> (mg/L)             | F (mg/L)                            |

|             | SD     | 12.15     | 1.01                   | 80.65                  | 135.87                        | 73.32                          | 3.09      | 0.47                                       | 3.18                                    | 1.1      | 5.77                                | 5.57                                |

To further identify the factors contributing to NO<sub>3</sub><sup>-</sup> contamination of groundwater in the study area, a PCA based on 18 parameters (temperature, ORP, pH, DO, EC, TDS, Ca<sup>2+</sup>, Mg<sup>2+</sup>, Na<sup>+</sup>, K<sup>+</sup>, HCO<sub>3</sub><sup>-</sup>, F<sup>-</sup>, Cl<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, Br, I, and Si<sup>4+</sup>) was performed. The Kaiser-Meyer-Olkin (KMO) and Bartlett's tests were used to prove the competence of the PCA. The KMO value was 0.70 ( $p < 0.05$ ), and Bartlett's sphericity test was significantly different from the identity correlation matrix ( $p < 0.05$ ); hence, the results from the PCA were validated and provide

significant reductions in dimensionality. The first two eigenvectors (PC1 and PC2) from the PCA are depicted in **Fig.3.3**, which includes the scores of each sampling site on both principal components (the complete dataset is provided in **Table A.2.1** in **Appendix 2**), which together explained 78.3% of the total variance in the dataset.

**Fig. 3.3.** Compositional clr-biplot showing the relationship between major and minor components with  $\text{NO}_3^-$  sources (the PCA was carried out using the data from **Table A.2.1**)

The first quadrant in **Fig. 3.3** is located in the opposite direction of the  $\text{NO}_3^-$  ray, indicating that this area (green ellipse) comprises the most  $\text{NO}_3^-$ -depleted samples (group 3). The second quadrant (II) in **Fig.3.3** is in the direction of the  $\text{NO}_3^-$  ray on the PC2 axis, which indicates an increase in the  $\text{NO}_3^-$  concentration (groups 2 and 3, blue ellipse). Quadrants III and IV depict the positive scores of PC1, which correspond to the most  $\text{NO}_3^-$ -rich samples (group 1, red ellipse). Both quadrants were associated with M&S sources because contamination of groundwater derived from domestic sewage typically presents significant enrichments of  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$  (Held et al., 2007; Vystavna et al., 2019; Wang et al., 2019), as well as natural fertilizers (manure as organic-N), which agrees with the land use/land cover.

### 3.3.2 Isotopic composition of water

The  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  and  $\delta^2\text{H}_{\text{H}_2\text{O}}$  values of groundwater samples from CLR ranged from -12.51‰ to -6.31‰, and -86.72‰ to -50.82‰, respectively, with no significant differences among the three groups. **Fig. 3.4a** displays the  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  versus  $\delta^2\text{H}_{\text{H}_2\text{O}}$  values, which fell below the global meteoric water line (GMWL; Rozanski et al., 1993) and the local meteoric water line (LMWL; Aguilar-Ramírez et al., 2017). The linear evaporation trend in the dataset ( $\delta^2\text{H}_{\text{H}_2\text{O}} = 5.6\delta^{18}\text{O}_{\text{H}_2\text{O}} - 15.37$ ) reflects the groundwater recharge's evaporation process. As a slope of > 5 is atypical for a semi-arid climate, the observed trend suggests the mixing of evaporated soil water with infiltrated rainwater/recirculated agricultural water (Clark and Fritz, 1997; Mahlknecht et al., 2008). Deuterium excess varied mostly between 0‰ and 10‰ (**Fig. 3.4b**), which infers that a post-condensation evaporative effect was associated with the groundwater samples (Clark and Fritz, 1997; Mahlknecht et al., 2008). Although the TDS concentration of the samples ranged widely (257- 4874 mg/L), the  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  value was relatively stable at around -9‰ (**Fig. 3.4c**). This suggests that direct evaporation enriched stable isotopes, but it was not the leading cause of the increased TDS concentration (Jia et al., 2017). From these observations, it can be concluded that there are at least two recharge processes in the CLR: (1) recharge from mountainous areas (groups 2 and 3); and (2) vertical aquifer recharge from rainfall or anthropogenic activities (group 1, **Fig. 3.4c**), as evidenced by the evolution trend of the Cl<sup>-</sup> concentration (i.e., irrigation return flow or sewage leakages).

**Fig. 3.4.** a) Plot showing the mean values of  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  and  $\delta^2\text{H}_{\text{H}_2\text{O}}$  in groundwater of the CLR; GMWL is the global meteoric water line (Rozanski et al., 1993) and LMWL is the local meteoric water line proposed by Aguilar-Ramírez et al. (2017) for northeastern Mexico. b) TDS concentration compared to d-excess. c)  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  vs.  $\text{Cl}^-$  concentration. Note: the three groups determined by the HCA are shown in different colors: red triangles (group 1), blue squares (group 2), and green circles (group 3).

### 3.3.3 Isotopic composition of nitrate

The  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  value of the groundwater samples in the study area ranged from 8.86‰ to 39.67‰ and -0.93‰ to 14.89‰, respectively (**Table 3.1**). In the absence of previous nitrate isotope studies for the CLR, the results were compared to typical end-members' values reported in the literature reviews (Section 3.2.5). Based on these reviews, the  $\delta^{15}\text{N}_{\text{NO}_3}$  values in the samples were higher than those reported in the literature for synthetic fertilizers (from -6‰ to 6‰). All 53 samples fell between the overlapped range reported for  $\text{NO}_3^-$  originating from SON (from +3‰ to +8‰), sewage (+4‰ to +19‰), and manure (+5‰ to +35‰). The  $\delta^{18}\text{O}_{\text{NO}_3}$  values in the samples from the CLR were lower than those reported for AD (+25‰ to +75‰) and synthetic fertilizers (+17‰ to +25‰). However, the  $\delta^{18}\text{O}_{\text{NO}_3}$  values of 16 samples were within the range reported for M&S (+0.5‰ to +5‰), and the  $\delta^{18}\text{O}_{\text{NO}_3}$  values of 18 samples were between those of M&S and the theoretical value of  $\text{NO}_3^-$  derived from nitrification (+10‰). Eight samples were above the microbially-produced  $\text{NO}_3^-$ , although these  $\delta^{18}\text{O}_{\text{NO}_3}$  values could have also been associated with the same origin if  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  was enriched due to the evaporative process (Xue et al., 2009). Although the  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  values were of different ranges and exhibited diverse N sources, there were no significant statistical differences ( $p > 0.05$ ) among the three groups of samples.

## 3.4 Discussion

### 3.4.1 Nitrate sources and attenuation interpreted by chemical indicators

The  $\text{NO}_3^-$  (as N) concentrations ranged from 0.01 to 109 mg/L, with 58% of the samples (mostly belonging to groups 1 and 2) exceeding the threshold value (3 mg/L) for anthropogenic influence (Ogrinc et al., 2019), thus highlighting the severity of  $\text{NO}_3^-$  contamination problem in the study area. The findings suggest that  $\text{NO}_3^-$  contamination during the study period was due to leakages from the sewage systems, manure, and/or agricultural inputs. Likewise, 32% of the samples contained a  $\text{NO}_3^-$  concentration that exceeded the maximum permissible limit (10 mg/L as N) for safe drinking water established by the World Health Organization (WHO, 2017). The lowest  $\text{NO}_3^-$  concentrations were found at sites T07, T08, and T09 (mean groundwater depth of 113 m), which can be attributed to

the absence of human impact, coupled with their proximity to local groundwater recharge areas. Elevated  $\text{NO}_3^-$  concentrations were found at sites T11 (109 mg/L), B14 (74.8 mg/L), or B03 (45 mg/L), where the water table depth was 134, 158, and 90 m below ground level, respectively, and which are areas associated with the long-term application of fertilizers or manure.

Chloride is usually considered an essential conservative tracer because it is generally inert to biological or chemical transformations in hydrologic systems (Clark and Fritz, 1997). As a tracer,  $\text{Cl}^-$  is useful for identifying anthropogenic pollution sources such as sewage leakage, fertilizers, manure, and natural sources (e.g., rainfall or the dissolution of  $\text{Cl}^-$ -bearing minerals) that can increase the  $\text{Cl}^-$  concentrations. A significant positive correlation ( $r_s = 0.61, p < 0.001$ ) was found between  $\text{NO}_3^-$  and  $\text{Cl}^-$  in the sampled groundwater of CLR; hence, it can be assumed that manure and sewage are potential sources of  $\text{NO}_3^-$  (Kohn et al., 2015; Rao, 2006) (**Fig. 3.5b**). In this study, the  $\text{NO}_3^-/\text{Cl}^-$  ratios were used to distinguish whether  $\text{NO}_3^-$  was derived from agricultural inputs, SON inputs, or sewage inputs (**Fig. 3.5a**). The elevated  $\text{Cl}^-$  concentration and low  $\text{NO}_3^-/\text{Cl}^-$  ratios (**Fig. 3.5a**) in groundwater samples in group 1 indicate that  $\text{NO}_3^-$  was derived from M& S (Widory et al., 2005). Group 3 was associated with the lowest  $\text{Cl}^-$  concentrations and lowest  $\text{NO}_3^-/\text{Cl}^-$  ratios, thus indicating the extent of  $\text{NO}_3^-$  derived from soil inputs (Guo et al., 2020). Group 2 did not fit in the range of any specific potential  $\text{NO}_3^-$  input, which suggests that  $\text{NO}_3^-$  was derived from mixing between soil, sewage, and agricultural sources. Samples with a  $\text{NO}_3^-/\text{Cl}^-$  ratio equal to 1 could be associated with a mixture of agricultural inputs.

**Fig. 3.5.** a) Variation of Cl<sup>-</sup>-molar concentrations contrasted with NO<sub>3</sub><sup>-</sup>/Cl<sup>-</sup>-molar ratios of groundwater samples collected in the CLR (adapted from Guo et al., 2020; Widory et al., 2005); b) Scatterplot of TDS vs. (NO<sub>3</sub><sup>-</sup> + Cl<sup>-</sup>)/HCO<sub>3</sub><sup>-</sup>

Furthermore, according to **Fig. 3.5b**, the samples within groups 2 and 3 contained a TDS concentration of < 1000 mg/L, whereas group 1 exhibited a TDS concentration of up to ~5 000 mg/L. A (NO<sub>3</sub><sup>-</sup>+Cl<sup>-</sup>)/HCO<sub>3</sub><sup>-</sup> ratio of < 1 for groups 2 and 3, as some samples of group 1 were observed. The samples with a relatively high HCO<sub>3</sub><sup>-</sup> concentration could be attributed to the anoxic biodegradation of organic matter (**Eq. 3.3**, Jørgensen et al., 2004).

On the other hand, most of the samples in group 1 had a (NO<sub>3</sub><sup>-</sup> + Cl<sup>-</sup>)/HCO<sub>3</sub><sup>-</sup> ratio of > 1, which exhibited a weak positive correlation with the TDS concentration ( $r^2=0.37$ ). This suggests that urea employed in the study area at the time of sampling had suffered hydration (**Eq. 3.4**), which generated an enrichment of HCO<sub>3</sub><sup>-</sup> and promoted the nitrification of ammonium (NH<sub>4</sub><sup>+</sup>) (**Eqs. 3.5, 3.6**). Moreover, urban and rural sewage contains a large amount of NH<sub>4</sub><sup>+</sup> (Galloway, 2003), which may have contributed to the relatively high NO<sub>3</sub><sup>-</sup> concentrations in the water samples.

### 3.4.2 Nitrate sources and biogeochemical processes in the studied groundwater

Nitrogen transformations such as nitrification, denitrification, and volatilization are biogeochemical processes inherent to shallow aquifers. We found no clear correlations between  $\text{NO}_3^-$  and  $\delta^{15}\text{N}_{\text{NO}_3}$  or  $\delta^{18}\text{O}_{\text{NO}_3}$  ( $r_s = -0.01$  and  $r_s = 0.34$ , respectively) in the groundwater samples from the CLR, thus indicating that multiple mixing and biogeochemical processes were responsible for the measured  $\text{NO}_3^-$  concentrations. **Fig. 3.6a** plots  $\delta^{15}\text{N}_{\text{NO}_3}$  vs.  $\delta^{18}\text{O}_{\text{NO}_3}$  and includes the isotopic composition of the primary  $\text{NO}_3^-$  sources and possible biogeochemical processes (Vitòria et al., 2004; Xue et al., 2009).

Local  $\delta^{18}\text{O}_{\text{NO}_3}$  values can be used to estimate the contribution of  $\text{NO}_3^-$  derived from the nitrification of  $\text{NH}_4^-$ . This contribution can be described by the experimental equation (Andersson and Hooper, 1983), which suggests that it is necessary to incorporate two molecules of oxygen from water and one molecule from dissolved oxygen from atmospheric oxygen for the nitrification process (**Eq. 3.7**).

$$\delta^{18}\text{O}_{\text{NO}_3} = 2/3 \delta^{18}\text{O}_{\text{H}_2\text{O}} + 1/3 \delta^{18}\text{O}_{\text{O}_2} \quad (\text{Eq. 3.7})$$

where  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  represents the measured values in the groundwater samples, and  $\delta^{18}\text{O}_{\text{O}_2}$  represents the value for atmospheric oxygen (taken to be +23.5‰) (Aravena and Mayer, 2010). The results revealed that the observed  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  values in the study area ranged from -12.5‰ to -6.3‰ (**Fig. 3.6b**). The expected values of  $\delta^{18}\text{O}_{\text{NO}_3}$  derived from the nitrification of  $\text{NH}_4^-$  contained in precipitation, fertilizers, or soil should fall between -0.5‰ and 3.6‰ (identified by the grey area shown in **Fig. 3.6a**).

**Fig. 3.6.** a) Bi-plot of  $\delta^{15}\text{NNO}_3$  versus  $\delta^{18}\text{ONO}_3$ . The range of end-members values for the potential sources in the study area was adapted from literature (Kendall, 1998; Xue et al., 2009). b) Plot of  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  versus  $\delta^{18}\text{ONO}_3$ , where the line (1) represents the limit of exchange with  $\text{O}_2$ , line (2) represents the limit of the nitrification process, and line (3) shows the limit of exchange with  $\text{H}_2\text{O}$ . c) Scatterplot contrasting pH with DO, where the dashed line divides the trends for nitrification (right side) and denitrification (left side) processes. d) Plot showing the  $\delta^{15}\text{NNO}_3$  and  $\ln(\text{NO}_3^-)$  values in the CLR. Note: the samples belonging to the three different statistical groups are shown in different colors.

**Fig. 3.6a** confirms the existence of one or more biogeochemical processes that masked the nitrate isotopic composition derived from the original sources in the CLR. Hence, by taking into account the nitrification factors of DO with values  $> 4\text{mg/L}$  and a pH range of between 6.5 and 8 (Nikolenko et al., 2018) (**Fig. 3.6c**), it can be inferred from **Fig. 3.6a** that the  $\text{NO}_3^-$  in groundwater samples T23, T22, B28, and B26 (group 3); B19 and B20 (group 2); and T21 and T17 (group 1) were entirely from nitrification. On the other hand, samples T12, B17, and T15 (group 1) were associated with a mixing process, whereby partial nitrification contributed an estimated 49%, 63%, and 84% of the  $\text{NO}_3^-$ , respectively.

Another process is denitrification, which involves the natural attenuation producing a reduction of  $\text{NO}_3^-$  concentration and a release of  $\text{HCO}_3^-$ ,  $\text{CO}_2$ , or  $\text{SO}_4^{2-}$ . If denitrification occurs, the  $\delta^{15}\text{N}_{\text{NO}_3}$  or  $\delta^{18}\text{O}_{\text{NO}_3}$  values become elevated and follow a positive linear relationship in the residual  $\text{NO}_3^-$ , with a  $\delta^{18}\text{O}_{\text{NO}_3}/\delta^{15}\text{N}_{\text{NO}_3}$  ratio in the range of 1:1.13 to 1:2.1 (Böttcher et al., 1990; Fukada et al., 2003). Some samples (B04, B18, T05, T12, B17, and T15) fell into the ideal zone for denitrification in **Figs. 3.6a-c**, as revealed by an increase of the  $\delta^{15}\text{N}_{\text{NO}_3}$  values and a decrease of  $\text{NO}_3^-$  along the groundwater flow path. Denitrification resulting from the oxidation of organic matter should lead to a decrease in the  $\text{NO}_3^-$  concentration and a simultaneous increase of  $\text{HCO}_3^-$  concentration.

Similarly, the relationship between  $\delta^{15}\text{N}_{\text{NO}_3}$  and the logarithmic concentration of  $\text{NO}_3^-$  ( $\ln(\text{NO}_3^-)$ ) was employed to understand better the processes occurring in the groundwater system. **Fig. 3.6d** shows that all of the samples followed a negative slope. Groups 1 and 3 negative slopes with low correlations ( $r^2=0.040$  and  $0.045$ , respectively) suggest a mixing process, whereas group 2 exhibited a moderate correlation ( $r^2=0.64$ ), which suggests that a denitrification process could have been responsible for the shifting values of  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$ .

The isotopic enrichment of certain samples (e.g., B1, B3, B08, B12, B13, B14) could be explained by an  $\text{NH}_4^+$  volatilization process, which can occur within the pH range of these samples (**Eq. 3.8**, Kendall, 1998). In the CLR, manure is produced as dry matter at 1 000 000 t/year, typically used as a natural fertilizer without pretreatment (Acevedo Peralta et al., 2017; Figueroa Viramontes et al., 2015). Thus,  $\text{NH}_4^+$  volatilization is favored during storage (before use) and after spreading (Nikolenko et al., 2018; Shalev et al., 2015; Vitòria et al., 2008).

### 3.4.3 Apportionment of $\text{NO}_3^-$ sources based on the MixSIAR model

A Bayesian mixing model was used to estimate the probability distribution of the proportional contributions of  $\text{NO}_3^-$  in combination with land-use/land-cover information for the study area, from which six potential sources were obtained (**Table A.3.1 of Appendix 3**). The MixSIAR

model outputs showed a similar pattern across the different groups, with a low contribution ( $\sim 10\%$ ) of four potential sources: AD, SON, NOF, and NHF (**Fig. 3.7 a-c**); meanwhile, M&S had the highest contribution for all the groups. To simplify the model, manure is referred to as the leaks derived from the storage in confined feeding operations (CAFOs) in the study area, and the manure spread used as a natural fertilizer.

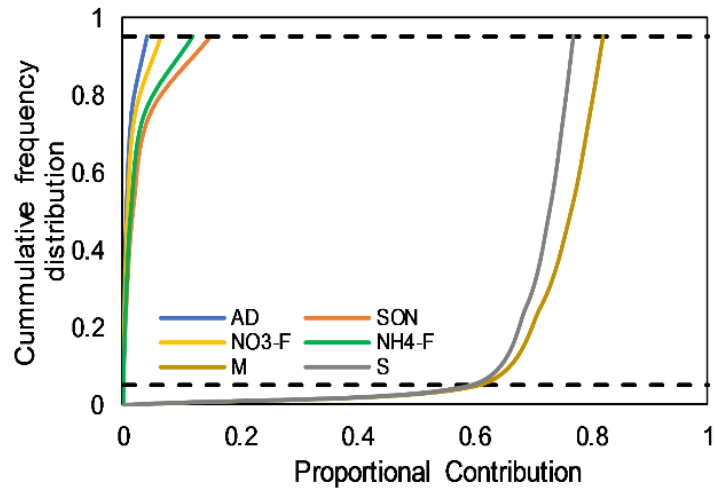

**Fig. 3.7.** Proportional contributions of the primary potential  $\text{NO}_3^-$  sources estimated by the MixSIAR model. Boxplots illustrate the 25th, 50th, and 75th percentiles; the whiskers indicate 5th and 95th percentiles. Note: the order a, b, c corresponds to groups 1, 2, and 3. The different  $\text{NO}_3^-$  sources are shown in different colors.

For the entire study area, the percentage contribution of  $\text{NO}_3^-$  sources was ranked as:  $M > S > SON > NHF > NOF > AD$ . Thus, that of AD was the lowest at  $1.2 \pm 1.5\%$  of all of the samples. This agrees with findings from other temperate to dry areas (Li et al., 2019; Matiatos, 2016; Torres-Martínez et al., 2020a; Xue et al., 2012) and is in accordance with the low annual rainfall in the study area. The percentage contribution of SON was similar for groups 1 and 3 ( $3.0 \pm 4.8\%$  and  $2.8 \pm 4.1\%$ , respectively), which were lower than that of

group 2 ( $7.9 \pm 9.2\%$ ). This agrees with the lower  $\text{NO}_3^-/\text{Cl}^-$  ratios and lower  $\text{Cl}^-$  concentrations in **Fig. 3.5a**. Further, NOF and NHF contributed means of  $1.7 \pm 2.4\%$  and  $3.0 \pm 4.5\%$ . However, the most significant source of  $\text{NO}_3^-$  to groundwater in the study area was from M&S, with mean contributions of  $47.7 \pm 4.3\%$  (M) and  $42.6 \pm 4.3\%$  (S), which are consistent with **Figs. 3.3** and **3.55a**. Thus, during sampling, the CLR was mainly polluted by anthropogenic inputs from leakage of the municipal sewage system in metropolitan areas, septic tanks leakage in rural communities, and the intensive application of manure as an organic fertilizer. Even though the CLR is an important agricultural area of Mexico, our results indicate that synthetic fertilizers were not the main cause of elevated  $\text{NO}_3^-$  concentrations during our study.

The sum of the estimated proportional contributions should be equal to 1 (**Fig. 3.8**). However, each estimated contribution is a probability distribution in a particular range. Thus, an uncertainty index ( $\text{UI}_{90}$ ) was calculated as the difference between the proportional contribution of 0.95 and 0.05 (considering the rapid increase segment of 90%), divided by 0.9, to characterize the uncertainty strength. Overall, AD and NOF were relatively stable, showing a  $\text{UI}_{90}$  of 0.05 and 0.07, respectively. Besides, NHF and SON exhibited similar  $\text{UI}_{90}$  values (0.13 and 0.17, respectively), whereas the highest uncertainty was associated with M (0.24) and S (0.20). The increased uncertainty in M and S sources could be attributed to isotope fractionation during the different transformation processes along the groundwater flow path that affects the isotopic fingerprint.

**Fig. 3.8.** Cumulative probability distributions for proportional contributions of the different potential  $\text{NO}_3^-$  sources based on MixSIAR results. Note: the different  $\text{NO}_3^-$  sources are shown in different colors.

In summary, six different potential  $\text{NO}_3^-$  sources were identified in the CLR and evaluated by combining the results of major ion chemistry, stable isotopes, and MixSIAR, a Bayesian isotope mixing model. The findings of this chapter could provide technical support for stakeholders aiming to improve water quality management in the CLR. As urban sewage and manure applications were by far the primary sources of groundwater  $\text{NO}_3^-$ , local authorities should consider rehabilitating the sewage pipelines used to collect industrial and domestic sewage in urban areas. Furthermore, there is a need to enhance the treatment, management, and disposal of manure for agricultural activities. Considering that manure is the main fertilizer used in the study area, it is necessary to minimize its overuse and establish a manure regulatory policy because there is no strict regulation in Mexico (Acevedo Peralta et al., 2017).

Although our results provide essential information for identifying, evaluating, and controlling  $\text{NO}_3^-$  concentrations in groundwater, there are some limitations. It should be noted that the MixSIAR model allows an estimation of the proportional contribution of  $\text{NO}_3^-$  sources with relatively low uncertainty values inherent to  $\text{NO}_3^-$  inputs. Another uncertainty exists because most production wells have an open casing (full-screened) regardless of the depth. Hence, the collected samples in this research are a mix of different circulation depths, which also contributed to the uncertainty in the model results. We note that, although the findings revealed the source contributions at a specific season (autumn), there was no rain during

our sampling, and temporal changes over the entire year may have been negligible due to the predominantly dry climate. Further investigations based on additional isotope tracers (e.g.,  $\delta^{11}\text{B}$ ,  $\delta^{34}\text{S}$ ,  $\delta^{87}\text{Sr}/^{86}\text{Sr}$ ,  $\delta^{13}\text{C}$ ) could help to improve the understanding of the different biogeochemical processes and pollution sources that affect the N cycle in the selected study area.

### 3.5 Conclusion

This chapter exhibited an example of using hydrochemical compositions and isotopic fingerprints ( $\delta^2\text{H}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ) in combination with a Bayesian isotope mixing model to elucidate the sources, transformations, and contributions of  $\text{NO}_3^-$  pollution in the overexploited groundwater of the arid CLR in Mexico. The results showed that 58% of the groundwater samples from the CLR exceeded the threshold for anthropogenic inputs, and 32% exceeded the WHO's safe drinking water limit of 10 mg/L. From this, a low (<3 mg/L; group 3), moderate (<10 mg/L; group 2) and high (>10 mg/L; group 1)  $\text{NO}_3^-$  concentrations zones were identified.

$\text{NO}_3^-$  in the groundwater was derived from multiple sources, including soil organic nitrogen (SON), synthetic fertilizers (NHF and NOF), manure, urban sewage, and precipitation. Results showed that using a Bayesian isotope mixing model in combination with land-use and land-cover maps could be successfully applied to estimate proportional contributions of non-point  $\text{NO}_3^-$  sources, confirming that leakage derived from the intensive use of manure (~48%) and urban sewage or septic tanks leakages (~43%) were the primary  $\text{NO}_3^-$  pollution sources in the CLR. In comparison, synthetic fertilizers (~5%) and SON (~4%) contributed less to the enhancement of  $\text{NO}_3^-$  concentration in groundwater. Furthermore, by combining isotopic fingerprints ( $\delta^2\text{H}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ), a substantial nitrification process was identified as the predominant transformation in samples from recharge areas. Contrarily, samples from discharge areas were influenced by a denitrification transformation, which agrees with the low  $\text{NO}_3^-$  concentrations. Otherwise, transition-zone samples showed a combination of different biogeochemical processes: nitrification, denitrification, and volatilization.

# Chapter 4: La Paz Aquifer

## Case

This chapter is adapted from the submitted article

J.A. Torres-Martínez, A. Mora, J. Mählknecht, D. Kaown, D. Barceló, 2020. *Determining nitrate and sulfate pollution sources and transformations in a coastal aquifer impacted by seawater intrusion—A multi-isotopic approach combined with Self-organizing maps and a Bayesian mixing model.* **Under review**

## 4.1 Introduction

The human population is unevenly distributed globally, and the majority of economic development has occurred along rivers and coastal areas (Erostate et al., 2020; Grimm et al., 2008; Rodrigues Braga et al., 2020). Coastal zones are attractive for multiple reasons, such as an abundance of different natural resources, access to marine trade or transport opportunities, and the provision for recreational activities. However, increasing urban sprawls also causes radical changes in coastal environments, including land-use changes and increasing environmental pollution. This creates a severe demand for natural resources, exacerbated by a lack of government planning and management (Erostate et al., 2020; Neumann et al., 2017; Sterzel et al., 2020). Arid coastal areas are mainly dependent on groundwater resources, which, together with accelerated population growth, generates water stress and often leads to groundwater contamination due to seawater intrusion into freshwater resources.

The coastal aquifer system of La Paz, Mexico, is an example of an arid urban environment with prolonged periods of drought, relying on groundwater to satisfy the needs of approximately 270,000 inhabitants, 3,800 ha of agricultural land, and more than 320,000 tourists per year (INEGI, 2017; SIAP, 2018b). A lack of proper water management policies has resulted in over-drafting of the aquifer system, promoting an inversion in the hydraulic gradient, which has triggered the seawater intrusion. Previous research on this coastal aquifer system has focused on hydrogeological characterization (CONAGUA, 1997; Cruz-Falcón, 2007; Cruz-Falcón et al., 2010), assessing seawater intrusion using groundwater flow models (CONAGUA, 2001; Escolero and Torres-Onofre, 2007; Monzalvo, 2010; Torres-Martínez et al., 2019), and evaluating groundwater quality (CONAGUA, 2010, 2001; Cruz-Falcón et al., 2017; Torres-Martínez et al., 2017). Additionally, some studies have assessed the groundwater flow (Tamez-Meléndez et al., 2016) and seawater intrusion (Mahlknecht et al., 2017) in that zone using multi-isotopic techniques. This suggests that elevated  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  concentrations could be attributed to agricultural practices in the area, contributing to groundwater quality degradation. Nevertheless, the aforementioned studies did not use conclusive tools to support this assumption.

Almost all previous studies have focused only on water quality problems due to seawater intrusion. However, human-derived pollution is a significant reason for deteriorating water quality; such pollution results mainly from non-point sources, including agricultural practices or leaks in the sewage system, leading to  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  groundwater pollution. Although distinguishing  $\text{NO}_3^-$  or  $\text{SO}_4^{2-}$  sources in coastal environments is a complicated task, it is vital to establish opportune management plans because both substances can damage human health (Blaisdell et al., 2019; Sharma and Kumar, 2020) and result in adverse biota effects (Gomez Isaza et al., 2020; Sharma and Kumar, 2020).

A typical method for differentiating  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  pollution sources is the use of the dual-stable isotopic compositions of nitrate ( $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$ ) and sulfate ( $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$ ). Unfortunately, despite the ability of the dual-isotope plot to trace the origin of  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  contamination, uncertainties remain because two or more sources may sometimes overlap, hindering the correct differentiation of the origin (Nikolenko et al., 2018; Wang and Zhang, 2019). Moreover, the biogeochemical transformations in the environment affect the isotopic fingerprint, which complicates the source's identification. To avoid overlapping-related issues in nitrate source identification, some studies have utilized a combination of different techniques, using stable nitrate isotopes in conjunction with halide ratios (Pastén-Zapata et al., 2014; Torres-Martínez et al., 2020a), boron isotopes (Kruk et al., 2020; Lasagna and De Luca, 2019), multivariate statistical methods (Guo et al., 2020; Matiatos, 2016; Torres-Martínez et al., 2020b), microbiological approaches (Romanelli et al., 2020; Zhu et al., 2019), and multi-isotopic approaches (Li et al., 2020; Pittalis et al., 2018; Zhang and Wang, 2020). Although the identification of  $\text{SO}_4^{2-}$  sources in groundwater has not been studied extensively, some studies have combined sulfate isotopes with carbon isotopes (Han et al., 2016; Hosono et al., 2014) and multi-isotopic (Hosono et al., 2011b; Puig et al., 2013) or bacterial approaches (Valiente et al., 2017) to elucidate the origins of sulfate in groundwater.

Several methods have also been used to develop a reliable technique for providing quantitative estimates of natural and anthropogenic nitrate sources' contribution to the total nitrate pool in specific groundwater environments. These methods include using analytical and mathematical tools such as mass balance calculations (Degnan et al., 2016; Janža et al., 2020), end-member mixing analysis (Grimmeisen et al., 2017; Ogrinc et al., 2019), and

statistical models such as multi-linear regression analysis (Meghdadi and Javar, 2018b) and the Bayesian isotope mixing model (BIMM)(Cui et al., 2020; Gibrilla et al., 2020; Kazakis et al., 2020; Torres-Martínez et al., 2020b). In contrast, to estimate the contribution of different sulfate sources, only a few methods have been developed using chemical mass balance models (Sun et al., 2021; Xu et al., 2016), end-member mixing models (Chen et al., 2020), and BIMMs (Torres-Martínez et al., 2020a; Q. Zhang et al., 2020).

To the best of our knowledge, no environmental studies have estimated the proportion of seawater-derived sulfate in coastal aquifers affected by seawater intrusion using a dual-isotope sulfate analysis combined with a BIMM. Therefore, the objectives of this chapter are 1) to assess the nitrate and sulfate concentrations in groundwater from the La Paz aquifer; 2) to identify the sources of  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  in groundwater using multiple stable isotopes; and 3) to quantify the apportionment of different potential  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  pollution sources (including seawater-derived sulfate) using a BIMM. This study is the first to estimate the contribution and uncertainty of seawater-derived  $\text{SO}_4^{2-}$  using  $^{34}\text{S}_{\text{SO}_4}$  and  $^{18}\text{O}_{\text{SO}_4}$  combined with the BIMM.

## 4.2 Materials and methods

### 4.2.1 Study area

The La Paz aquifer system is situated in the eastern part of the California Gulf in the northeastern region of Mexico (**Fig. 4.1**). The morphological architecture of the La Paz region is characterized by a coastal plain (valley) enclosed by plateaus and mountain ranges that reach heights of 1,266 m above sea level. The geology of the area is composed of metamorphic, volcanic, and sedimentary formations (**Fig. A3.1**). Metamorphic rocks (gneiss, shales, and metasedimentary rocks) deposited from the Jurassic (Mesozoic Era) are found in the basement. Beyond this unit in the basin's mountainous part, Cretaceous volcanic rocks (mainly gabbro, granite, and granodiorite) emerge in the eastern region of the area, constituting the Las Cruces mountain range. In the western part, Neogene sedimentary rocks (sandstones and conglomerates) and fractured volcanic rocks (rhyolitic tuff and basalt) are present. In the central lowlands of the valley, Holocene deposits consisting of

unconsolidated alluvial deposits (sands, gravels, silts, and clays) and marine sediments are found (Hirales Rochin and Urcadiz Cazares, 2019; INEGI, 1995; SGM, 2007).

The study area has a semi-desert climate, with average annual temperature and precipitation of 24 °C and 263 mm, respectively. Hence, the area exhibits an unbalanced distribution between rainfall and surface runoff because most of the precipitation occurs between July and October (hurricane season), accounting for more than 75% of the annual rainfall. Land use in the area is mainly urban and agricultural. Hence, the yearly water demand for agricultural, urban, and tourist activities is met with groundwater from the basin's aquifers. However, severe over-drafting has resulted in excessive chloride concentrations in the local groundwater due to seawater intrusion (Mahlknecht et al., 2017). On the other hand, the excessive use of N-based fertilizers has led to a considerable increase in  $\text{NO}_3^-$  concentrations in groundwater from agricultural regions, necessitating identifying the origin to establish  $\text{NO}_3^-$  management plans.

**Figure 4.1.** (a) Location of La Paz aquifer in northeastern Mexico; (b) delimitation of the aquifer using digital elevation model; and (c) land use/land cover, locations of the sampled sites, and main urbanized areas.

#### 4.2.2 Sample collection and analytical methods

Considering the different land uses, potential pollution sources, and geographical coverage, water samples from 46 production wells and one spring were collected in August 2013. Groundwater samples correspond to alluvial aquifers with well depths varying from 15 to 200 m (**Table 4.2**). Before obtaining the water samples, the production wells were drained until the pH, and electrical conductivity (EC) were stabilized to prevent water stagnation and obtain a representative groundwater sample. In-situ measurements of temperature, pH, dissolved oxygen (DO), and EC were performed using a multiparameter probe (Orion Star A329, Thermo Fisher Scientific). Bicarbonate species were determined through acid-base

titration using a 0.02-N solution of H<sub>2</sub>SO<sub>4</sub>. The collected samples were filtered through 0.45- $\mu$ m membranes and stored in triple-pre-rinsed low-density polyethylene bottles. Samples for cation analysis were acidified to pH 2 to prevent analyte losses, whereas samples for anion determination were placed in sampling kits without any preservative. All the samples for chemical analyses were maintained at 4 °C until analysis, whereas the samples for NO<sub>3</sub><sup>-</sup> and SO<sub>4</sub><sup>2-</sup> isotopes were frozen to -20 °C to minimize chemical reactions and prevent any alteration caused by biological processes.

Chemical analyses were conducted at Activation Laboratories Ltd. (Ancaster, Canada) according to the Standard Methods for the Examination of Water and Wastewater (APHA, 2012). Cations (Na<sup>+</sup>, K<sup>+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>) were measured using inductive-coupled plasma optical emission spectrometry (ICP-OES, Agilent Axial 730-ES), whereas anions (Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>) were measured using ion chromatography (IC, Dionex DX-120). The charge-balance error (%) was calculated, considering a 10% threshold as the acceptance criterion to validate the results.

The water stable-isotope composition ( $\delta^2\text{H}_{\text{H}_2\text{O}}$  and  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ) was measured at Tecnológico de Monterrey (Mexico) using off-axis integrated cavity output spectroscopy (OA-ICOS, LGR-DLT-100). The analytical procedure followed the methodology described by Berman et al. (2013), with accuracies of  $\pm 0.2\text{‰}$  and  $\pm 0.8\text{‰}$  for  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  and  $\delta^2\text{H}_{\text{H}_2\text{O}}$ , respectively. Nitrate isotopes ( $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$ ) and sulfate isotopes ( $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$ ) were measured at the Environmental Isotope Laboratory of the University of Waterloo (Canada). The nitrate isotopes were measured using a chemical reduction technique (Ti et al., 2018), which reduced NO<sub>3</sub><sup>-</sup> to NO<sub>2</sub><sup>-</sup> through a cadmium catalyst chemically converted to N<sub>2</sub>O for analysis using a trace-gas isotope-ratio mass spectrometer (TG-IRMS, GVI-IsoPrime). The analytical accuracy was  $\pm 0.3\text{‰}$  for  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\pm 0.8\text{‰}$  for  $\delta^{18}\text{O}_{\text{NO}_3}$ . The sulfate isotopic composition test ( $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$ ) was conducted by first acidifying the sample to a pH value of 3, followed by boiling and adding BaCl<sub>2</sub> to obtain BaSO<sub>4</sub>. Then, the BaSO<sub>4</sub> was oven-dried to 80 °C, before an element analyzer (EA, Elementar PreciSION-EA) coupled to a continuous-flow isotope-ratio mass spectrometer (CF-IRMS, GVI-Isoprime) was used. The analytical precisions for  $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$  were  $\pm 0.3\text{‰}$  and  $\pm 0.5\text{‰}$ , respectively.

All the stable-isotope ratios for H<sub>2</sub>O, NO<sub>3</sub><sup>-</sup>, and SO<sub>4</sub><sup>2-</sup> were expressed in delta values (δ), representing deviations in the per mil (‰) notation following international standards (**Eq. 4.1**):

$$\delta_{sample}(\text{‰}) = \frac{R_{sample} - R_{standard}}{R_{standard}} * 1000 \quad (\text{Eq. 4.1})$$

where  $R_{sample/standard}$  is the abundance ratios (D/H, <sup>15</sup>N/<sup>14</sup>N, <sup>34</sup>S/<sup>32</sup>S, or <sup>18</sup>O/<sup>16</sup>O) for the sample and standard, respectively; the standard for nitrogen isotope measurements pertains to atmospheric N<sub>2</sub>. For sulfur isotopes, measurements are in accordance with the Vienna Cañon Diablo Troilite (VCDT) standard. Finally, hydrogen and oxygen are reported in accordance with the Vienna Standard Mean Ocean Water (VSMOW).

#### 4.2.3 Interpretation techniques

##### 4.2.3.1 *Self-organizing maps*

Multivariate statistics is a common approach used for processing groundwater grouping data. However, an alternative tool for determining the hydrogeochemical similarities of complex environments is the self-organizing map (SOM). The SOM is an artificial neural network technique developed by Kohonen (Kohonen, 1982) to emulate the biological processes of human brains. This technique was designed to obtain a nonlinear dimensionality reduction in which similar inputs are physically located close to each other in neurons, preserving the data structure to summarize data with unsupervised classifications (Kohonen, 2013). SOM models have been effectively used in hydrology, hydrogeochemistry, and other water-related fields (Céréghino and Park, 2009; Clark et al., 2020; Kalteh et al., 2008).

The SOM algorithm consists of an input layer and an output layer of neurons (SOM layer), typically arranged on a hexagonal lattice grid. The input layer is wholly connected to the SOM layer through a weight vector ( $V_i$ ). The following procedure describes the SOM algorithm:

1. Data preprocessing. A transformation of the data is necessary before using the SOM method to ensure that all the hydrochemical parameters have the same relevance. In this study, all the variables were transformed using the compositional data technique known as centered log-ratio transformation (CLR). This transformation involves dividing each component ( $x$ ) by the geometric mean ( $g(X)$ ) of all variables, according to the following equation (**Eq. 4.2**):

$$clr(x_i) = \ln \frac{x_i}{g(X)} \quad (\text{Eq. 4.2})$$

2. Determination of the SOM structure. The optimal number of nodes (neurons) was estimated using the heuristic rule  $m = 5\sqrt{n}$  (Vesanto and Alhoniemi, 2000), where  $m$  is the total number of nodes, and  $n$  is the number of samples in the dataset.
3. Initialization of the weight vector ( $W_i$ ) with random values.
4. Identification of the winner neuron or best-matching unit, which is the closest match to the input vector, using the Euclidian distance,  $D$  (**Eq. 4.3**):

$$D = \sqrt{\sum_{i=1}^n ((V_i - W_i)^2)} \quad (\text{Eq. 4.3})$$

5. Continuation of the iterative training until the integrated distance criterion is minimized.
6. Post-processing of the SOM results. Visualization maps (unified distance matrix and component planes) are generated, and each node's reference vector is projected onto the maps.

In this study, the Kohonen package developed in the R environment (Wehrens and Buydens, 2007) was used to analyze the hydrochemical data. The input layer of the SOM consisted of a matrix of 5 field parameters (temperature, pH, DO, total dissolved solids (TDS), and EC) and 11 chemical parameters ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{HCO}_3^-$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Si}^-$ ,  $\text{Br}^-$ , and  $\text{As}^-$ ) of 47 water samples. Following the heuristic rules, a feature map with 42 ( $6 \times 7$ ) nodes was selected. The SOM model results were used with the k-means clustering algorithm to obtain an appropriate number of groups (Kim et al., 2020). After the groups were formed, the normality was analyzed for all groups using the Shapiro–Wilk test, and the difference in

variables between groups was evaluated using an ANOVA test ( $p < 0.05$ ). If the assumption of normality was rejected, the non-parametric Kruskal–Wallis test was applied.

#### 4.2.3.2 Estimation of contributions from different nitrate pollution sources

The proportional contributions of the different  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  pollution sources in the water samples were calculated using a Bayesian stable-isotope mixing model, which employs the Markov chain Monte Carlo method with a Bayesian framework. Models were implemented using the MixSIAR package (version 3.0.2) developed in an R environment. The methodology used in the MixSIAR model has been described in detail by Stock *et al.* (2018). The different isotopic compositions of nitrate and sulfate sources used in the model were obtained through a literature review (Nikolenko *et al.*, 2018; Torres-Martínez *et al.*, 2020a; Wang and Zhang, 2019; Xue *et al.*, 2009; Y. Zhang *et al.*, 2018b) and are listed in **Table 4.1**. The model parameters were set as 500,000 iterations with a burn-in of 50,000, a sample interval of 15, and an iteration maintainer of 30,000. Furthermore, an uncertainty index ( $UI_{90}$ ) defined by Ji *et al.* (2017) was applied to characterize the uncertainty based on the posterior distribution (**Eq. 4.4**) and then delineate the uncertainty associated with the apportionment of the pollution sources.

$$UI_{90} = \frac{PC_{90} - PC_{10}}{90} \quad (\text{Eq. 4.4})$$

where  $PC_{90}$  and  $PC_{10}$  denote the maximum and minimum proportional contribution values in the immediate increase segment with a 90% cumulative probability.

**Table 4.1.** Summary of  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ,  $\delta^{34}\text{S}_{\text{SO}_4}$ , and  $\delta^{18}\text{O}_{\text{SO}_4}$  isotopic signatures, from some possible end-members used in the MixSIAR model

| Source                      | $\delta^{15}\text{N}_{\text{NO}_3}$ | $\delta^{18}\text{O}_{\text{NO}_3}$ | $\delta^{34}\text{S}_{\text{SO}_4}$ | $\delta^{18}\text{O}_{\text{SO}_4}$ |
|-----------------------------|-------------------------------------|-------------------------------------|-------------------------------------|-------------------------------------|

## 4.3 Results

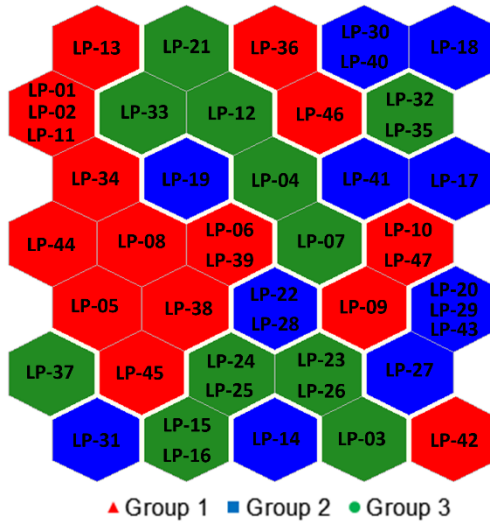

### 4.3.1 Water sampling grouping and hydrogeochemical characterization

The field measurements, chemical parameters, and isotopic ratios measured in the groundwater samples collected from the La Paz aquifer system are summarized in **Table 4.2** (complete database is presented in **Table A.3.1 of Appendix 3**). The map size used in the SOM model was 35 ( $5 \times 7$ ), with minimum quantization error and topographic error values of 0.02 and 0.01, respectively; this indicates that the SOM model results were optimal. **Fig. 4.2** shows a visualization of the different component planes of each hydrochemical parameter used in the iterative trained SOM map. Each component plane matrix denotes an index value obtained after dimension reduction, which instantly recognizes dependencies among hydrochemical variables through a gradient from white to red, corresponding to low and high values, respectively. Based on contrasting of the qualitative relations of the component plane maps,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{Cl}^-$  have similar color change gradients (increasing to the upper right), indicating a strong correlation, which is in agreement with the results obtained by Támez-Meléendez *et al.* (2016) through a Pearson correlation analysis. Conversely,  $\text{Na}^+$  and  $\text{SO}_4^{2-}$  exhibited an increasing trend to the lower left. The  $\text{K}^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{NO}_3^-$  ions did not follow patterns similar to those of the other major ions.

**Figure 4.2.** Component planes for major cations and anions: (a)  $\text{Ca}^{2+}$ , (b)  $\text{Mg}^{2+}$ , (c)  $\text{Na}^+$ , (d)  $\text{K}^+$ , (e)  $\text{HCO}_3^-$ , (f)  $\text{Cl}^-$ , (g)  $\text{SO}_4^{2-}$ , (h)  $\text{NO}_3^-$

Considering the hydrogeochemical conditions, the results obtained using the SOM model suggested that the groundwater chemistry in the study area could be divided into three groups according to their similarities and geographical correspondence, as shown in **Fig. 4.3**. Group 1 (18 samples, red shapes) represents fresh groundwater collected from the recharge areas (southern area of the aquifer), infiltration areas with treated wastewater (LP3-38 and LP-39), and the urbanized area of La Paz city. Group 2 (14 samples, blue shapes) represents fresh to brackish water sampled near agricultural areas. Finally, Group 3 (14 samples, green shapes) represents brackish water sampled close to the coastline, irrigated land, and the El Centenario and Chametla communities.

**Figure 4.3.** Pattern classification map of three clusters obtained by combining the SOM model and K-means algorithm. Numbers represent the Id of the water sampling points.

**Table 4.2.** Summary of descriptive statistics for physicochemical and isotopic parameters in La Paz aquifer

| Group         |      | Depth (m)               | T (°C)    | pH                     | DO (mg/L)              | SDT (mg/L)                                 | EC (µS/cm)                                | Ca (mg/L)                                | Mg (mg/L)                                  | Na (mg/L)                                  | K (mg/L)                                  |

|               | SD   | 251.4                   | 648.0     | 14.9                   | 111.9                  | 0.6  | 4.7                                       | 2.1                                      | 1.2  | 1.7  | 1.5                                       |

The depth of the production wells across the groups varied substantially, from 15 to 201 m below the surface; however, the depths of wells from Group 3 were significantly less ( $p < 0.05$ , mean  $43.4 \pm 20.5$  m) than those of the wells from both Groups 1 and 2. There were no significant differences between groundwater temperatures and pH among the three groups, with the mean values being  $29.8 \pm 1.7$  °C and  $7.3 \pm 0.3$ , respectively. The DO concentration

in Group 3 ( $6.3 \pm 1.2$  mg/L) was significantly lower ( $p < 0.05$ ) than that in Groups 1 and 2, which exhibited mean values of  $7.9 \pm 1.8$  and  $7.1 \pm 1.3$  mg/L, respectively. The mean TDS and EC values increased significantly ( $p < 0.01$ ) in the following order: Group 1 (TDS: 562.8 mg/L; EC: 844  $\mu$ S/cm) < Group 2 (TDS: 1,418.6 mg/L; EC: 2,101  $\mu$ S/cm) < Group 3 (TDS: 3,352 mg/L; EC: 5,087  $\mu$ S/cm).

The average concentrations of major anions ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ , and  $\text{K}^+$ ) increased significantly ( $p < 0.01$ ) in the following order: Group 1 ( $\text{Ca}^{2+}$ : 48.3 mg/L;  $\text{Mg}^{2+}$ : 18.7 mg/L;  $\text{Na}^+$ : 68.5 mg/L;  $\text{K}^+$ : 3.1 mg/L) < Group 2 ( $\text{Ca}^{2+}$ : 139.9 mg/L;  $\text{Mg}^{2+}$ : 45.0 mg/L;  $\text{Na}^+$ : 196.4 mg/L;  $\text{K}^+$ : 4.7 mg/L) < Group 3 ( $\text{Ca}^{2+}$ : 338.1 mg/L;  $\text{Mg}^{2+}$ : 141.5 mg/L;  $\text{Na}^+$ : 499.4 mg/L;  $\text{K}^+$ : 8.0 mg/L). Major cations ( $\text{HCO}_3^-$ ,  $\text{Cl}^-$ , and  $\text{SO}_4^{2-}$ ) exhibited significant increments in the following order: Group 1 ( $\text{HCO}_3^-$ : 228.1 mg/L;  $\text{Cl}^-$ : 138.7 mg/L;  $\text{SO}_4^{2-}$ : 24.2 mg/L) < Group 2 ( $\text{HCO}_3^-$ : 378.0 mg/L;  $\text{Cl}^-$ : 519.1 mg/L;  $\text{SO}_4^{2-}$ : 91.4 mg/L) < Group 3 ( $\text{HCO}_3^-$ : 597.7 mg/L;  $\text{Cl}^-$ : 1,462.0 mg/L;  $\text{SO}_4^{2-}$ : 243.9 mg/L). The  $\text{NO}_3^-$  concentrations of Group 3 had a mean value of  $15.6 \pm 14.9$  mg/L, which was significantly higher than the mean concentrations of Groups 1 and 2 ( $4.0 \pm 2.9$  and  $6.7 \pm 3.3$  mg/L, respectively).

The resulting clusters from the SOM model were used in the isometric log-ratio (ILR)-ion plot through compositional data analysis (Shelton et al., 2018) and the hydrochemical facies evolution diagram (HFE-D) developed by Giménez-Forcada (2010) to identify seawater intrusion phases (**Fig. 4.4**). The ILR plot suggests that cations from most of the samples of Groups 1, 2, and 3 were predominantly  $\text{Na}^+$  (bottom right in **Fig. 4.4a**), with the abundance decreasing in the order  $\text{Na}^+ > \text{Ca}^{2+} > \text{Mg}^{2+} > \text{K}^+$ . In contrast, anions from Groups 1, 2, and 3 were primarily  $\text{Cl}^-$  in the areas near the coastline; the order of abundance was  $\text{Cl}^- > \text{HCO}_3^- > \text{SO}_4^{2-}$  (upper right in **Fig. 4.4a**). However, some samples of Group 1 from the southern part of the aquifer (recharge area) were dominated by  $\text{HCO}_3^-$ , with the order of abundance being  $\text{HCO}_3^- > \text{Cl}^- > \text{SO}_4^{2-}$ . Furthermore, the HFE-D (**Fig. 4.4b**) confirmed that 83% of the samples in the study area were in the seawater intrusion phase and that only 17% were in the freshening phase (recharge areas).

**Figure 4.4.** a) Isometric log-ratio (ILR)-ion plot; and b) Hydrochemical facies evolution diagram (HFE-D)

#### 4.3.2 Stable isotopic compositions

In this study, the isotopic compositions of  $H_2O$ ,  $NO_3^-$ , and  $SO_4^{2-}$  were measured to track the origin of these ions (natural and anthropogenic sources) and identify the different biogeochemical transformations involved in the groundwater system. A summary of the results is given in **Table 4.2**.

The  $\delta^{15}\text{N}_{\text{NO}_3}$  and  $\delta^{18}\text{O}_{\text{NO}_3}$  isotopic compositions of the groundwater samples in the study area ranged from 6.1‰ to 23.9‰ and from -2.2‰ to 8.6‰, respectively (**Table 4.1**). As this study represents the first multi-isotopic assessment of tracing nitrate and sulfate pollution in the La Paz aquifer, the results were compared with typical end-members reported in the literature reviews (Fenech et al., 2012; Gutiérrez et al., 2018; Nikolenko et al., 2018; Xue et al., 2009). Because  $\text{NO}_3^-$  concentrations in seawater are at trace levels, a  $\text{NO}_3^-$  seawater end-member was not considered in the dual-isotopic analysis. Contrasting the results with these reviews, the  $\delta^{15}\text{N}_{\text{NO}_3}$  values in most of the samples were in the overlapping zone between soil organic nitrogen (SON; from -0.5‰ to +8‰) and sewage (Se; from +9.6‰ to +25.2‰). The  $\delta^{18}\text{O}_{\text{NO}_3}$  values in the samples from the La Paz aquifer were significantly lower than those reported for synthetic fertilizers (SF; +17‰ to +25‰) (Nikolenko et al., 2018). Nevertheless, the  $\delta^{18}\text{O}_{\text{NO}_3}$  values of 17 samples were within the range reported for SON and Se (from -1.7‰ to +6.47‰ and from -0.3‰ to +12.1‰, respectively); 1 sample above the field near to the theoretical value of  $\text{NO}_3^-$  derived from nitrification (+10‰) suggesting a shifting in the isotopic composition typical from denitrification and the  $\delta^{18}\text{O}_{\text{NO}_3}$  values of 28 samples were below +0.5‰. The  $\delta^{15}\text{N}_{\text{NO}_3}$  isotopic compositions of Group 3 exhibited significantly higher values ( $p < 0.05$ ) than Groups 1 and 2, whereas the  $\delta^{18}\text{O}_{\text{NO}_3}$  values were not significantly different between the three groups.

On the other hand, the  $\delta^{34}\text{S}_{\text{SO}_4}$  and  $\delta^{18}\text{O}_{\text{SO}_4}$  values in groundwater covered wide compositional ranges, from +1.5‰ to +19.3‰ and from +2.2‰ to +15.8‰, respectively (**Table 4.1**). According to literature (Torres-Martínez et al., 2020a; Wang and Zhang, 2019) and land use/land cover information on the study area, the  $\delta^{34}\text{S}_{\text{SO}_4}$  values are widely dispersed among different sources: atmospheric deposition (AD), soil-derived  $\text{SO}_4^{2-}$  (SS), synthetic fertilizers (SF), sewage (Se), detergents (De), and seawater (SW). Three samples fell into the overlapping area between SS, Se, and SF (-4.2‰ to +12.7‰); two samples were between the boundaries of AD and SS (-4.2‰ to +7.2‰); nine samples were in the SF (-4.1‰ to +12.7‰) area, and the remaining samples were in a transition region between the previous sources and SW. Most of the  $\delta^{18}\text{O}_{\text{SO}_4}$  values in La Paz were lower than those reported for AD (+6.6‰ to +12.9‰), SF (+7.8‰ to +16.3‰), De (+12.0‰ to +17.2‰), and SW (+8.0‰ to +12.8‰), falling in the typical ranges for SS (+3.7‰ to +5.6‰) and Se (+3.8‰ to +10.0‰).

## 4.4 Discussion

### 4.4.1 Nitrate pollution sources and biogeochemical processes

Nitrate concentrations (as N) in the study area ranged from 0.2 to 48.8 mg/L. Among the groundwater samples, 66% had a nitrate concentration exceeding 3 mg/L—the threshold considered as a result of human influence (Ogrinc et al., 2019)—and 23% exhibited values over 10 mg/L (the maximum permissible limit for drinking water, as determined by WHO (WHO, 2017)); this highlighted the critical impact of anthropogenic  $\text{NO}_3^-$  inputs on water quality. The lowest concentrations were found at sampling sites LP-09, LP-10, LP-47 (1.4, 1.5, and 1.7 mg/L, respectively), with no influence of anthropogenic activities. In contrast, elevated  $\text{NO}_3^-$  concentrations were detected at sites LP-31 (48.8 mg/L) and LP-27 (45.8 mg/L) near the rural communities of Chametla and El Centenario, respectively.

To identify the qualitative information related to the different pollution sources responsible for the increase in  $\text{NO}_3^-$  concentrations in groundwater samples from the study area, a dual-isotope biplot was drawn according to the nitrate isotopic signatures. It was contrasted with land-use/land-cover maps (**Fig. 4.5a, b**). Based on this plot, none of the groundwater nitrate isotopic fingerprints fell into the AD source area, suggesting a minimum contribution directly from precipitation. In contrast, SON and S were identified as the dominant nitrate sources in most water samples (**Fig. 4.5a**), suggesting an increase in  $\delta^{15}\text{N}_{\text{NO}_3}$  resulting from a mixing process. Also, the SON was the primary source in non-urban areas (**Fig. 4.5b**). None of the samples fell in the typical synthetic fertilizer range despite the agricultural activities; thus, it was assumed that the isotopic composition from fertilizers had been masked by different biogeochemical processes (Romanelli et al., 2020; Saccon et al., 2013).

**Figure 4.5.**  $\delta^{15}\text{N}_{\text{NO}_3}$  vs.  $\delta^{18}\text{O}_{\text{NO}_3}$  plot according to the land-use/land-cover information in (a) urban and (b) agricultural areas; Relationship between (c)  $\delta^{15}\text{N}_{\text{NO}_3}$  and (d)  $\delta^{18}\text{O}_{\text{NO}_3}$  vs.  $1/\text{NO}_3^-$  concentrations

Most nitrogen transformations depend directly on environmental conditions, such as pH, Eh, DO, and the chemical compositions of the media. Nitrification of  $\text{NH}_4^+$  remineralized from the soil is a nitrate production process, generally involving microbes, which is favored under conditions of  $\text{DO} > 4 \text{ mg/L}$  and pH values oscillating between 6.5 and 8 (Nikolenko et al., 2018; Rivett et al., 2008). The result of this process is an increase in  $\text{NO}_3^-$  concentration and a depletion in the  $\delta^{18}\text{O}_{\text{NO}_3}$  and  $\delta^{15}\text{N}_{\text{NO}_3}$  isotopic compositions (Kendall, 1998).  $\delta^{18}\text{O}_{\text{NO}_3}$  is a sensitive tracer for identifying the nitrification process in aquatic environments. Theoretical values of  $\delta^{18}\text{O}_{\text{NO}_3}$  derived from nitrification are often assumed to contribute to a 2:1 ratio of oxygen exchange with  $\text{H}_2\text{O}$  during nitrification and the relative contribution from the atmosphere ( $0.66\delta^{18}\text{O}_{\text{H}_2\text{O}} + 0.33\delta^{18}\text{O}_{\text{O}_2}$ ) (Boshers et al., 2019; Snider et al., 2010). The theoretical values obtained for nitrification based on a ratio of 2:1 were estimated using the

local water isotopic composition, which ranged from -11.6 to -7.1‰ ( $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ), and assuming an  $\delta^{18}\text{O}_{\text{O}_2}$  value of +23.9‰ for atmospheric oxygen (Mader et al., 2017).

**Figure 4.6.**  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$  vs.  $\delta^{18}\text{O}_{\text{NO}_3}$  with theoretical values of  $\delta^{18}\text{O}_{\text{NO}_3}$  derived from nitrification

The obtained  $\delta^{18}\text{O}_{\text{NO}_3}$  values of the nitrate derived from nitrification were, on average,  $1.9 \pm 0.7\%$ . Most of the values fell into the theoretical nitrification range, as shown in **Fig. 4.6**. Nevertheless, LP-26, LP-27, LP-28, LP-33, LP-45, and LP-47 exhibited values higher than the estimated values for full equilibrium with the  $\delta^{18}\text{O}$  of groundwater. This could be attributed to the mineralization–immobilization–turnover process (MIT) in LP-26, LP-27, and LP-28. The MIT process results from the microbial immobilization of  $\text{NO}_3^-$  as organic N, followed by mineralization from organic N to  $\text{NH}_4^+$  and, finally, a nitrification process (Jahangir et al., 2020; Minet et al., 2012; Puig et al., 2017). This process results in the  $\delta^{18}\text{O}$  depletion of the  $\delta^{18}\text{O}_{\text{NO}_3}$  from the synthetic fertilizers typically employed in the region (Beltrán-Morales et al., 2019; Cardona et al., 2004; Ceseña, 2015). Although elevated DO ( $>4$  mg/L) is not the optimal environmental condition for this process, recent research by Utom *et al.* (2020) indicated that denitrification does not always occur under strictly anaerobic conditions. Hence, samples LP-33, LP-45, and LP-47, which exhibited higher  $\delta^{18}\text{O}_{\text{NO}_3}$  isotopic compositions and lower  $\text{NO}_3^-$  concentrations, could be affected by a

bacterial denitrification process (Kendall et al., 2008). On the other hand, an increase in  $\delta^{15}\text{N}_{\text{NO}_3}$  values was observed (**Fig. 4.5b**). This isotopic fractionation could be attributed to ammonia volatilization due to the use of synthetic fertilizers combined with alkaline soil conditions ( $\text{pH} > 8$ ) (López-Méndez et al., 2013) and the subsequent production of nitrified nitrate (Choi et al., 2017; Mariotti et al., 1988; Minet et al., 2012).

Additionally, to further assess the different nitrate biogeochemical processes, the  $\delta^{15}\text{N}_{\text{NO}_3}$  results were evaluated against nitrate concentrations. The Keeling plot (**Fig. 4.5c–d**) exhibited values of  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ , and  $\text{NO}_3^-$  with negative relationships and no significant correlations (0.28 and 0.03, respectively) in all groups, confirming that the denitrification process did not influence the nitrate isotopic composition in the study area.

#### 4.4.2 Sulfate pollution sources and biogeochemical processes

The sulfate concentration of samples collected in the study area ranged from 7.9 to 490 mg/L. Among the water samples, 10.6% had sulfate concentrations exceeding 250 mg/L, the recommended threshold for drinking water consumption (WHO, 2017). The lowest concentrations were found at sampling sites LP-06, LP-10, LP-47 (10.8, 9.8, and 7.9 mg/L, respectively), with no influence of anthropogenic activities or seawater intrusion. In contrast, elevated  $\text{SO}_4^{2-}$  concentrations were detected at sites LP-22 (490 mg/L) and LP-27 (316 mg/L) near the coastline in the Chametla community.

Upon analyzing the dual-isotope biplot approach of sulfate isotopic compositions for urban (**Fig. 4.7a**) and agricultural (**Fig. 4.7b**) areas, it was found that samples LP-08 and LP-09 were close to the SS range, which was in agreement with the results for the non-urbanized land-use area and the local reference for this pollution source. Only one sample (LP-37) fell into the AD source area, suggesting that precipitation contributes minimal  $\text{SO}_4^{2-}$  levels in groundwater. In urbanized and agricultural areas, samples exhibited a  $\delta^{34}\text{S}_{\text{SO}_4}$  enrichment (**Fig. 4.7a–d**) with no changes in the  $\text{SO}_4^{2-}$  concentration, suggesting the occurrence of a mixing process with an isotopically heavy end-member, which could be marine evaporites or seawater intrusion. However, according to Mahlkecht *et al.* (2017), there is no evidence of marine sulfate evaporites (gypsum) in the study area, indicating that according to the isotopic fingerprints, the dominant mixing process is between soil and seawater pollution

sources. This finding is confirmed by the vertical trend shown in **Fig. 4.7c–d** (Das et al., 2011).

Samples from Groups 2 and 3 in urbanized areas were enriched in the  $\delta^{34}\text{S}_{\text{SO}_4}$  isotopic fingerprint and exhibited decreasing  $\text{SO}_4^{2-}$  concentrations, suggesting a microbial sulfate reduction process (**Fig. 4.7c**) (Canfield, 2018; Tuttle et al., 2009; Yuan and Mayer, 2012). However, microbial sulfate reduction is typical in anoxic seawater and marine sediment porewater (Szynkiewicz et al., 2008). Overall, the groundwater showed aerobic conditions that do not favor microbial sulfate reduction; this indicated that reduction does not currently influence the groundwater's sulfate isotopic composition. Indeed, this process might have occurred in the past in marine-derived sulfate that had undergone sulfate reduction (Hosono et al., 2014; Szynkiewicz et al., 2008), with the  $\delta^{34}\text{S}_{\text{SO}_4}$ -enriched sulfate now being dragged by the upconing of deeper saline groundwater in the aquifer system. The lower values of  $\delta^{18}\text{O}_{\text{SO}_4}$  in most samples (**Fig. 4.7e–f**) indicated that microbial processes in soils control the isotopic compositions of samples (Szynkiewicz et al., 2015).

**Figure 4.7.**  $\delta^{34}\text{S}_{\text{SO}_4}$  vs.  $\delta^{18}\text{O}_{\text{SO}_4}$  plot according to land-use/land-cover information in (a) urban and (b) agricultural areas; Relationship between (c–d)  $\delta^{34}\text{S}_{\text{SO}_4}$  and (e–f)  $\delta^{18}\text{O}_{\text{SO}_4}$  vs.  $\text{SO}_4^{2-}$  concentrations in urban and agricultural areas.

#### 4.4.3 Nitrate and sulfate source apportionment combined with uncertainty approach

Although the dual-isotope biplot approach provided relevant qualitative information about the different pollution sources, it is necessary to ascertain the amount  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  derived from the previously identified sources (Section 4.4.1 and 4.4.2). Hence, a quantitative estimation of the contributions was performed using a BIMM through MixSIAR to provide decision-makers and other stakeholders relevant and precise information to improve water pollution control strategies. Based on previous analyses, no denitrification process was identified in this study, and therefore, the isotopic fractionation factor was not considered in the model.

As shown in **Fig. 4.8a–b**, results obtained from the MixSIAR model indicate that for  $\text{NO}_3^-$  pollution, SON contributed the largest amount of  $\text{NO}_3^-$  to the aquifer system ( $72.0 \pm 10.2\%$ ,  $\sim 4.56$  mg/L), followed by Se ( $26.3 \pm 9.0\%$ ,  $\sim 3.54$  mg/L), SF ( $1.5 \pm 2.6\%$ ,  $\sim 0.16$  mg/L), and AD ( $0.2 \pm 0.4\%$ ,  $\sim 0.02$  mg/L). Notably, although the output model values indicated that SON was the dominant source (71.5%), sewage leaks had a severe impact, which, at only 26.3%, has an equitable contribution to SON in terms of  $\text{NO}_3^-$  concentration. **Fig. 4.10c–d** depicts the proportional contributions of the different  $\text{SO}_4^{2-}$  pollution sources in the entire study area. Seawater (SW), with  $43.0 \pm 7.9\%$ , contributes (as indicated in **Fig. 4.4b**) on average, 55.55 mg/L of sulfate, followed by soil-derived sulfate (SS), with  $42.0 \pm 10.7\%$  ( $\sim 46.71$  mg/L). The remaining amount is contributed by detergents ( $5.9 \pm 1.9\%$ ,  $\sim 1.33$  mg/L), synthetic fertilizers ( $4.3 \pm 3.1\%$ ,  $\sim 2.93$  mg/L), precipitation ( $3.6 \pm 3.5\%$ ,  $\sim 1.76$  mg/L), and sewage ( $1.2 \pm 1.6\%$ ,  $\sim 0.91$  mg/L).

**Figure 4.8.** (a) Average global proportional contributions of four potential nitrate pollution sources estimated using the MixSIAR model (in percentage) and (b)  $\text{NO}_3^-$  concentration as N (mg/L); (c) Average global proportional contributions of six potential sulfate pollution sources estimated using the MixSIAR model (in percentage) and (d)  $\text{SO}_4^{2-}$  concentration (mg/L)

In recent research, it was found that small variations or overlapping in isotopic values might result in considerable changes in the source apportionment values generated by the mixing model (Torres-Martínez et al., 2020b; H. Zhang et al., 2020); this incorporates uncertainty into the estimation of the proportional contributions (**Fig. 4.9**). In the case of  $\text{NO}_3^-$  sources (**Fig. 4.9a**), AD exhibited the lowest average  $\text{UI}_{90}$  values (0.01), followed by SF (0.09), Se (0.32), and SON (0.33). In the case of  $\text{SO}_4^{2-}$  sources (**Fig. 4.9b**), Se and De exhibited the lowest average  $\text{UI}_{90}$  values (0.05 and 0.06, respectively), whereas AD and SF showed similar uncertainties (0.10). Finally, SW and SS exhibited the highest values, 0.29 and 0.38, respectively.

**Figure 4.9.** Cumulative distributions of the proportional contributions of (a) four potential nitrate sources and (b) six potential sulfate sources.

Despite the considerable uncertainty in some parameters, the  $UI_{90}$  values obtained using the  $NO_3^-$  isotope mixing model was significantly less in comparison with previous findings, which were in the range of 0.05–0.20 for AD, 0.48–0.63 for SON, 0.17–0.67 for SF, and 0.24–0.46 for Se (Ji et al., 2017; Shang et al., 2020; Torres-Martínez et al., 2020b). There is no comparison for the  $SO_4^{2-}$  isotope mixing model because this is the first uncertainty assessment performed. A significant source of uncertainty was the typical open-casing (full-screened) construction of production wells in Mexico; a mixing sample derived from different groundwater circulation depths was obtained (Knappett et al., 2020; Torres-Martínez et al., 2020b). Therefore, to reduce uncertainty in future research, it is necessary to obtain the isotopic composition from discrete depths of the aquifer to further constrain local pollution sources and provide narrow, accurate end-member ranges.

In summary, groundwater quality deterioration is currently controlled by two factors. First is aquifer mismanagement, with a lack of extraction regulations, which impacts the hydrogeological system conditions modifying the groundwater flow path. Overexploitation in the study area has led to a significant decrease in groundwater levels (Torres-Martinez et al., 2019), thereby increasing the thickness of the vadose zone. This promotes artificial conditions favored by the nitrification process (Kazakis et al., 2020; Xin et al., 2019) and promotes seawater intrusion, thereby increasing sulfate pollution. Second, there is a significant  $\text{NO}_3^-$  contribution due to the lack of maintenance of the sewage system, resulting in leaks and the absence of municipal infrastructure in rural areas (~13% of households) connected to the sewage system (CEA, 2015).

Finally, this chapter highlights that groundwater nitrate and sulfate pollution require particular attention for effective soil management under the  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  input control strategies. It is necessary to establish a periodic sampling campaign (including increasing the number of sampling sites), which would improve the understanding of the biogeochemical transformations that affect the isotopic composition from the different pollution sources and would further aid in identifying the possible effects associated with changes in the hydrogeological flow path.

## **4.5 Conclusion**

In this chapter, nitrate and sulfate groundwater pollution sources, their proportional contributions, and the different biogeochemical processes associated with groundwater contamination in the La Paz aquifer system were evaluated using hydrochemical and multi-isotopic datasets with a BIMM.

The multi-isotopic approach showed that groundwater nitrate mainly originated from soil organic nitrogen and its mixing with leaks from the domestic sewage system. Furthermore, nitrification was identified as the most critical biogeochemical process favored by the expansion of the vadose zone due to the overuse of the aquifer, whereas denitrification was not considered due to the aerobic conditions of the study area. Despite the use of fertilizers for agricultural activities, it was impossible to identify fertilizers' contribution using the nitrate isotopic fingerprints due to a masking ammonia volatilization process. Meanwhile, sulfate

pollution was primarily caused by the mixing of soil-derived sulfate with an intense seawater intrusion process. No significant sulfate fractionation process was identified (e.g., sulfur oxidation or reduction).

The results obtained using the Bayesian model confirmed that soil organic nitrogen and leaks from the sewage system were responsible for the elevated nitrate concentrations (~72.0% and ~26.3%, respectively), exceeding the maximum permissible limit for drinking water (10 mg/L) in 23% of the samples. In contrast, only 10% of the water samples exceeded the recommended maximum level of sulfate concentration for human consumption (250 mg/L), and sewage leaks were not a significant sulfate pollution source (~1.2%). Nevertheless, similar to nitrates' case, the soil was considered a significant sulfate pollution source (~42%), with an equal contribution from seawater intrusion (~43%), which was evaluated for the first time using this methodology employed in this study.

# **Chapter 5: Synthesis and outlook**

## 5.1 Introduction

This thesis is proposed in response to the limited understanding of groundwater nitrate and sulfate pollution origin and fate in aquifers from northern Mexico. The knowledge about nitrate and sulfate source and transformation processes would help to improve groundwater pollution management. The main objective of this thesis was:

- Evaluate the processes that control groundwater chemistry and identify and quantify the contribution of different nitrate and sulfate sources in different aquifer systems.

The doctoral research outcomes are summarized in this chapter to highlight their scientific contribution evaluating the main objective in different scenarios. Following a summary of the findings, future scientific research is proposed based on the outcomes of this thesis for advancing the research in this field.

## 5.2 Summary of the findings

The main objective of this research was to evaluate the processes that control the chemistry of groundwater and identify and quantify the contribution of different nitrate and sulfate pollution sources in different semi-arid aquifer systems. The research executed to meet the objective is discussed in detail from Chapter 2 to Chapter 4 and is summarized below.

In **Chapter 2**, the application of a suite of chemical and isotopic tracers ( $\delta^2\text{H}_{\text{H}_2\text{O}}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ,  $\delta^{34}\text{S}_{\text{SO}_4}$ ,  $\delta^{18}\text{O}_{\text{SO}_4}$ ) combined with a probability isotope mixing model to identify and quantify the nitrate and sulfate pollution sources in an industrialized area was discussed (Monterrey Metropolitan Area case). Results suggested that soil nitrogen and sewage were the most critical nitrate sources, while atmospheric deposition, marine evaporites, and sewage were the most prominent sulfate sources. However, the nitrate and sulfate concentrations were controlled by denitrification and sulfate reduction processes in the transition and discharge zones. The approach followed in this chapter is useful for establishing effective pollution management strategies in contaminated aquifers. In this chapter, the  $\text{SO}_4$  pollution derived from different sources was quantified for the first time worldwide using a Bayesian mixing model.

**Chapter 3** identifies nitrate ( $\text{NO}_3^-$ ) sources, and biogeochemical transformations controlling diffuse pollution in groundwater were evaluated in an affected area by intensive livestock and agricultural activities (Comarca Lagunera Region case). This chapter combines chemical data, including environmental isotopes ( $\delta^2\text{H}_{\text{H}_2\text{O}}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ), and also incorporates land use/land cover data to better understand the results of the Bayesian isotope mixing model and to reduce the uncertainty when estimating the contributions of different pollution sources. Furthermore, an uncertainty analysis for the Bayesian model was done. According to the groundwater flow path, different biogeochemical transformations were observed throughout the study area: microbial nitrification was dominant in the groundwater recharge areas with elevated  $\text{NO}_3^-$  concentrations; in the transition zones, a mixing of different transformations, such as nitrification, denitrification, and/or volatilization, was identified, associated to moderate  $\text{NO}_3^-$  concentrations; whereas in the discharge the primary process affecting  $\text{NO}_3^-$  concentrations was denitrification, resulting in low  $\text{NO}_3^-$  concentrations. The MixSIAR isotope mixing model results revealed that the application of manure from concentrated animal feeding operations (~48%) and urban sewage (~43%) were the primary contributors to N pollution. In contrast, synthetic fertilizers (~5%), soil organic nitrogen (~4%), and atmospheric deposition played a less critical role. Finally, an estimation of an uncertainty index (UI90) of the isotope mixing results indicated that the uncertainties associated with atmospheric deposition and  $\text{NO}_3^-$  fertilizers were the lowest (0.05 and 0.07, respectively), while those associated with manure and sewage were the highest (0.24 and 0.20, respectively). The uncertainty analysis used in **Chapter 3** is useful for contaminated aquifers.

In **Chapter 4**, an overexploited coastal agricultural aquifer was analyzed (La Paz aquifer case). Previous studies on the study area focused mainly on seawater intrusion, resulting in limited information on nitrate and sulfate pollution. Therefore, pollution sources have not yet been identified sufficiently. In this chapter, an approach combining hydrochemical tools, multi-isotopes ( $\delta^2\text{H}_{\text{H}_2\text{O}}$ ,  $\delta^{18}\text{O}_{\text{H}_2\text{O}}$ ,  $\delta^{15}\text{N}_{\text{NO}_3}$ ,  $\delta^{18}\text{O}_{\text{NO}_3}$ ,  $\delta^{34}\text{S}_{\text{SO}_4}$ ,  $\delta^{18}\text{O}_{\text{SO}_4}$ ), self-organizing maps, and a Bayesian isotope mixing model was used to estimate the contribution of different nitrate and sulfate sources to groundwater, evaluating for the first time  $\text{SO}_4$  derived from seawater intrusion. Moreover, an uncertainty assessment (UI90) was performed, and the potential biogeochemical transformations occurring in the coastal aquifer system were observed. Results from the MixSIAR model revealed that seawater intrusion and soil-derived

sulfates were the predominant sources of groundwater sulfate, with contributions of ~43.0% ( $UI_{90} = 0.29$ ) and ~42.0% ( $UI_{90} = 0.38$ ), respectively. Similarly, soil organic nitrogen (~72.0%,  $UI_{90} = 0.33$ ) and urban sewage (~26.3%,  $UI_{90} = 0.33$ ) were the primary contributors of nitrate pollution in groundwater. The dominant biogeochemical transformation for  $\text{NO}_3^-$  was nitrification. Denitrification and sulfate reduction were discarded due to the aerobic conditions in the aquifer system. Results of **Chapter 4** indicate that dual-isotope sulfate analysis combined with MixSIAR models is a powerful tool for estimating sulfate sources' contributions (including seawater-derived sulfate) in the groundwater of coastal aquifer systems affected by seawater intrusion.

### 5.3 Comparison with other study cases

From the results obtained in this doctoral research and contrasting them with other studies, it is possible to observe in **Table 5.1** that, despite the existence of differences between nitrate concentrations in the different environments represented by the study areas, in terms of contributions, atmospheric deposition oscillates between 0.2 and 2%, except for two cases Chengdu Plain and Asopos Basin with 18%. In the case of nitrate derived from organic decomposition, the results vary widely, ranging from 3 to 72%. Manure and sewage differ only in two case studies: La Comarca Lagunera Region and Chengdu Plain. Finally, fertilizers' use contributes between 1.5 and 60% to the contamination of groundwater by nitrates.

**Table 5.1.** Summary of nitrate contributions derived from Bayesian mixing models in different study cases

| Study Area                  | Reference             | Precipitation (mm/year) | Land Use                | $\text{NO}_3^-$ (mg/L) | AD   | SON   | Manure | Sewage | M&S   | Fertilizers |

On the other hand, regarding groundwater contamination associated with sulfates (**Table 5.2**), only three studies have been developed, representing different environments. Regarding atmospheric deposition, La Paz aquifer and Laizhou present similar contributions of 3.6 and 3.3%, respectively, significantly differing from Monterrey Metropolitan Area (24.9%), despite having an annual precipitation which is similar to the Chinese case. Regarding sewage, Monterrey Metropolitan Area and Hebei Province, a contribution of 37 to 45% is reported. Sulfide oxidation was only detected in China's case, while seawater intrusion was only reported in the La Paz aquifer adjacent to the Ocean. Regarding contamination by fertilizers, with low percentages of 4.3-9.7% were identified in La Paz and the China case.

**Table 5.2.** Summary of sulfate contributions derived from Bayesian mixing models in different study cases

| Study Area                  | Reference          | Precipitation (mm/year) | Land Use                        | SO <sub>4</sub> (mg/L) | AD    | SS    | Evaporite | Sewage | Sulfide oxidation | Seawater | SF   |

## 5.4 Future research

In general, this doctoral research results from the Bayesian isotope mixing modeling were consistent with interpretations based on previous hydrochemical and isotopic data. However, one limitation of this approach is that the isotopic ranges of sources were derived from literature. For this reason, further investigations to constrain the isotopic and chemical composition of local end-members is necessary to reduce the variance and uncertainty of the results. Moreover, it could be useful to try different isotopic or microcontaminants as

tracer combinations in the mixing models to clarify the origin of groundwater pollution in complex systems.

On the other hand, it is necessary to establish groundwater quality baselines and create long-term monitoring networks during different seasons, which would improve the understanding of the biogeochemical transformations that affect the isotopic composition from the different pollution sources and would further aid in identifying the possible effects associated with changes in the hydrogeological flow path in time and space.

Further investigations based on the combination of additional isotope tracers (e.g.,  $\delta^{11}\text{B}$ ,  $\delta^{34}\text{S}$ ,  $\delta^{87}\text{Sr}/^{86}\text{Sr}$ ,  $\delta^{13}\text{C}$ ) could help to improve the understanding of the different biogeochemical processes and pollution sources. Similarly, the use of microorganisms, micropollutants, and pesticides as co-tracers would help for a more robust conceptualization of contamination paths and evaluation of mitigation measures in a complex groundwater system.

# Appendix 2

## A2. Hydrogeological characteristics

### A.2.1 Principal-Lagunera Region

The Principal-Lagunera Region aquifer is included within an intermontane valley whose geological structure is mainly associated with folded sedimentary rocks (limestone, dolomite, gypsum, clayey sand, and conglomerate), eventually affected by intrusive igneous rocks (granite and volcanic deposits) (**Fig. A2.1**).

**Fig. A2.1.** Map showing the surface geology of the Comarca Lagunera Region, the groundwater table of 2017, and groundwater flow direction, including the location of the sampling sites in the CLR.

The geological succession in the Principal-Lagunera Region aquifer comprises (1) the Jurassic formation "Minas Viejas" which is composed of gypsum, lutites, and limestones; (2) the Cretaceous formations, "Aurora" formed by limestones and dolomites, "Indura" composed of lutites, limonites and limestones, and "Caracol" with lutites, clays, and sands; (3) the Tertiary formations, "Ahuichila" constituted of sandstones, limestones and conglomerates and "Santa Ines" which is also formed of limestones and conglomerates with a matrix of impermeable clay; finally (4) the Quaternary alluvium integrated by alluviums and terraces filling the stream channels and crowning older igneous rocks (This formation is considered the important aquifer).

The recent groundwater flow circulation has been modified from its natural condition (from the mountains near Torreón to the discharge areas in the Mayrán Lakes) by the increasing over-extraction from the around 3600 groundwater wells causing an inversion in the groundwater flow direction from the northeastern area in Los Remedios mountain range to the southwestern region where are situated the agricultural lands (CONAGUA, 2015a). The potentiometric surface in the area is around 100 m deep in the center of the depression and around 15 m deep in the areas near the mountains.

## A2.2 Villa Juárez

The general geology of the Villa Juárez aquifer is represented by sedimentary and igneous extrusive and intrusive rocks whose stratigraphic record comprises from Triassic-Jurassic to Recent. According to the geological information, the aquifer is constituted, in its upper portion, by alluvial, fluvial, and forest foot sediments, due to the weathering of rocks that work as a free aquifer. Below this formation, it is found a fractured medium with karsticity ("Cuesta del Cura" and "Aurora" formations), followed by limestones from the "Cupido" and "Zuloaga" formations.

In this aquifer, there are 55 groundwater wells mainly used by agricultural activities. The groundwater flow direction is in the Nazas river's direction, with a typical depth oscillating between 5 and 10 m from the surface.

### A2.3 Oriente-Aguanaval

The Oriente Aguanaval aquifer is made up of alluvial material and of sedimentary rocks, among which limestones and conglomerates stand out, which constitute 20% of the area each, whose rocks are of permeable to highly permeable characteristics. There are outcrops of extrusive igneous rocks in the center and south of the aquifer, such as basalt and acid tuff (CONAGUA, 2015b). The aquifer recharge is mainly derived from precipitation carried out on the mountains, plateaus, and hills, which infiltrates through the fractures in the volcanic rocks.

In this area, there are 310 groundwater wells whose exploitation generates an average depth to the water table is 55.3 m, and the groundwater flow follows the shape of the Aguanaval river in a direction from southeast to northwest leading to the Matamoros community.

### A2.4 Nazas

The geological succession in Nazas aquifer comprises (1) the Jurassic formations "La Casita," "La Gloria" and "Zuloaga" composed of gypsum, sandstones, and limestones; (2) the Cretaceous formations, "Cuchillo" and "Aurora" formed by limestones and dolomites, and "Indura" composed of lutites, limonites, and limestones; (3) the Tertiary formations, "Ahuichila" constituted of sandstones, limestones and conglomerates and "Santa Ines" which is also formed of limestones and conglomerates with a matrix of impermeable clay; finally (4) the Quaternary alluvium integrated which is made up clastic-granular materials of gravel, sand, and clay, and is considered the most permeable area from the region.

The Nazas aquifer is a shallow free-type aquifer with a typical depth oscillating between 15 and 24 m from surface and 211 groundwater wells. The groundwater flow direction is according to the direction of the Nazas river (CONAGUA, 2015c).

**Table A2.1.** Physical, chemical, and isotopic parameter of sampling points in the study area

# Curriculum Vitae

Juan Antonio Torres Martínez was born in Ciudad Madero, Tamaulipas, Mexico, on March 8th, 1990. He obtained a bachelor's degree in Civil Engineering at the Universidad Michoacana de San Nicolás de Hidalgo in 2014. During his bachelor's education, he worked on the characterization of historical drought events and estimation of its effects, considering climate change predictions. In 2016, he obtained a Master's in Science degree in Environmental Systems from the Tecnológico de Monterrey. During his Master's education, he worked on a groundwater flow model in Mexico's coastal aquifer at the Water Center for Latin America and the Caribbean. In 2017 he joined the doctoral program of the School of Engineering and Sciences at Tecnológico de Monterrey. His research was focused on groundwater quality issues (nitrate and sulfate pollution) in semi-arid zones of Northern Mexico, mainly using isotopic tools and Bayesian models. Throughout his Ph.D., he (co-) authored five articles and five conference papers in international peer-reviewed journals.
